Malignant tumors involving nerve typically require excision with a tumor-free margin. Exceptions include patients with normal or slightly impaired facial function, lymphomatous and leukemic invasion of the nerve, and low-grade malignancies of the parotid. In these cases, the tumors are removed while sparing the nerve.

FACIAL PALSY IN THE NEWBORN

Categories for facial palsy in the newborn include traumatic and congenital etiologies. Facial palsy secondary to birth trauma has an incidence of about 0.02%. Physical

signs of trauma include facial contusion, ecchymosis over the mastoid or course of the extracranial nerve, or a hemotympanum. Risk factors include forceps delivery, birth weight greater than 3,500 g, and primiparity (42). Thus, the mechanism of injury is likely to be compression due to molding of the head in passage through the birth canal or to the use of forceps. Within the first 3 days of life, an infant with complete facial paralysis should undergo electrical stimulation to demonstrate muscle contraction or evoked myogenic potentials. If trauma is not so evident, the information gained from the electrical tests provides conclusive evidence of neuromuscular integrity. For later presentations, NET, MST, and ENoG should be used initially, followed by EMG if myogenic responses are absent. The EMG may demonstrate insertional muscle activity, intact motor units, fibrillation potentials, or polyphasic motor units indicative of incomplete injury. The prognosis for spontaneous regeneration is excellent and surgical exploration is not recommended unless the nerve has had an opportunity for recovery (43).

Congenital palsy most commonly presents as a unilateral weakness of the lower lip and can be associated with other anomalies. Kobayashi (44) found no relationship of this limited form of palsy to the use of teratogenic drugs, rubella, birth trauma, or hereditary factors. More rarely, congenital facial palsies can present with other physical anomalies as part of a genetic syndrome. In Mobius syndrome, paralysis can result from congenital absence of the motor portion of the facial nerve and facial musculature or agenesis of the facial motor nucleus (45). Associated findings include unilateral or bilateral and complete or incomplete facial weakness, unilateral or bilateral abducens nerve palsy, and deformities of the extremities. Congenital paralysis is best left untreated until late childhood, as muscle transfers and fascial slings are often necessary for improved cosmesis. Because of the good skin turgor, the eye does not commonly require protective measures to prevent exposure keratitis in the child.

EYE CARE

The most common complication after the onset of facial paralysis is corneal desiccation. Complete paralysis, diminished tearing, loss of corneal sensitivity due to trigeminal nerve involvement, and absent Bell phenomenon are poor prognostic signs. At the onset, the patient should be advised of the signs of corneal irritation: itching, redness, foreign-body sensation, and visual blurring. Rubbing the eye is a sure sign of corneal irritation. Measures recommended for protection include the liberal use of ophthalmic lubricants, closure of the eye with tape at night, use of moisture chambers or shielded glasses, and avoidance of wind, vents, and fans. Patient education and fastidious treatment usually prevent the development of ulcers or scarring. If symptoms persist, ophthalmologic consultation is advised. Surgical treatment of the eye is rarely necessary in acute and temporary palsies. Patients with long-standing paralysis, corneal hypesthesia, and prior nerve repair with grafts are likely to require adjunctive management of the eye. Gold weight implants, canthoplasty, tarsorrhaphy, and upper eyelid springs are among the available surgical options.

HIGHLIGHTS

- Cranial nerve VII is composed of special visceral afferent, general visceral efferent, and special visceral efferent fibers, which provide taste, lacrimation, and mimetic functions respectively.
- The middle-ear and mastoid landmarks to the location of the facial nerve include the cochleariform process, the oval window, the horizontal semicircular canal, the chorda tympani nerve, and the digastric ridge.
- A paresis does not warrant electrophysiologic tests (NET, MST, ENoG), as the prognosis for recovery is good until the palsy is complete. Serial testing of a complete paralysis in the acute phase of degeneration provides the most accurate information on nerve injury and prognosis for recovery. EMG is the most reliable test for the evaluation of long-standing paralysis.
- Bell palsy accounts for more than half of acute facial palsy presentations. Any of the following make the diagnosis of Bell palsy less probable: a paresis evolving over a period exceeding 3 weeks, signs of neoplasia, trauma along the course of the nerve, vesicles on the head or neck, multiple cranial nerve involvement, temporal bone infection, palsy at birth, signs of central nervous system lesion, and failure to have any evidence of recovery 6 months after onset.
- Bell palsy patients demonstrate return to normal or near-normal function in 83% of cases without treatment. Experimental and clinical data implicate HSV as the likely causative agent. Medical therapy commonly includes steroids and antivirals, though the ability of these agents to alter prognosis remains controversial.
- The varicella zoster virus can produce facial paralysis. The hallmark of this infection is a vesicular eruption over the distribution of sensory afferent neurons of the cervical plexus or cranial nerves V, VII, IX, or X. The prognosis for functional recovery is poorer than in patients with Bell palsy. Antiviral therapy is recommended.
- For facial palsy presenting as a complication of infection, the immediate treatment should be directed toward eradicating the infection.

- Temporal bone fractures are the most common cause of traumatic injury to the facial nerve. Most injuries involve the nerve in the perigeniculate region or in the tympanic segment above the oval window. The most common finding at surgical exploration is contusion.
- The preferred order of procedures used to preserve the integrity of motor function of the facial nerve during management of skull base tumors is transposition or rerouting, division and reanastomosis, interpositional grafting, and cranial nerve crossover (XII to VII or XI to VII). Any anastomosis or grafting of the intracranial or intratemporal facial nerve will have synkinesis as a result.

156 Otologic Manifestations of Systemic Disease: Includes Autoimmune Inner Ear Disease

Arnaud F. Bewley *Michael J. Ruckenstein*

Numerous systemic diseases can affect the ear, causing a variety of otologic complaints including hearing loss, vestibular dysfunction, and facial nerve paresis. These diseases span a broad differential including infectious, granulomatous, autoimmune, bone, and metabolic etiologies (Table 156.1). Prior to progressing to systemic involvement, many can initially present as a process isolated to the ear. It is therefore critical that the otolaryngologist be aware of this broad differential when evaluating any otologic complaint. This chapter provides a systematic review of this differential, discussing the most pertinent examples of each etiology. The topic of autoimmune disease includes a discussion of autoimmune inner ear disease (AIED), a rare cause of sensorineural hearing loss (SNHL), given that what we know about the pathophysiology of this disease derives largely from our knowledge of how systemic autoimmune diseases affect the ear.

INFECTIOUS DISEASE

Infectious diseases are the most common type of systemic disease to manifest otologic pathology. Pathogens may infect the inner ear and auditory pathways *in utero*, resulting in congenital syndromes that often include deafness, or infection may be acquired after birth. As the fluids of the inner ear are not easily accessible for sampling, the implication of viral pathogens as the causes of otologic disease has often depended on circumstantial evidence, including an associated viral illness, like an upper respiratory infection, or demonstration of seroconversion during the time of hearing loss. In other cases, more direct evidence exists such as with CMV infection, where DNA has been amplified using PCR from perilymph obtained during cochlear implantation in children previously diagnosed with congenital infection (1).

Cytomegalovirus

Cytomegalovirus (CMV) is a large double-stranded DNA virus belonging to the herpes virus family. Its name derives from the typical appearance of infected tissues, containing massively enlarged cytomegalic inclusion cells. CMV is the most common congenital infection in the world. One percent of babies born in the United States are infected; the likely route of infection is transplacental. Of these babies, 10% will exhibit symptomatic infection, or cytomegalic inclusion disease, almost exclusively when primary maternal infection occurs during pregnancy (2). Of those babies that survive the neonatal period, the majority will have severe neurologic deficits and a severe bilateral SNHL. Possibly more significant, from an epidemiologic point of view, is hearing loss that develops in those children with apparently asymptomatic congenital CMV infection; between 7% and 15% of these infants will go on to develop SNHL. Most cases will be mild, but up to a quarter will be severe (3). Hearing loss may be unilateral or bilateral and may develop months or years after birth and be missed on routine audiometric screening. It is thought that asymptomatic CMV infection causes 20% to 30% of congenital hearing loss. In the healthy adult, CMV infection is usually asymptomatic or may cause a mononucleosis-like syndrome. In human immunodeficiency virus (HIV)-infected or transplant patients, severe multisystemic disease may ensue, but hearing loss is not common.

Rubella

Rubella is a member of the Togaviridae family. Primary maternal infection during the first trimester of pregnancy may result in congenital rubella syndrome. SNHL is the most common manifestation of this disease, seen in up to 60% of affected infants. Hearing loss may be bilateral or unilateral, may manifest as late as the second year of life, and may be the only sign of infection. Other features are ocular malformations, including cataract and retinopathy; cardiac malformations; and central nervous system (CNS) disease. Postnatal infection produces German measles, a mild viral illness (4).

TABLE 156.1 SYSTEMIC DISEASES WITH OTOLOGIC MANIFESTATIONS

Infectious diseases
- Viral infection
  - Varicella-zoster
  - Mumps
  - Measles
  - HIV
  - CMV
  - Rubella
- Bacterial infection
  - Syphilis
  - Lyme disease

Granulomatous disease
- Langerhans histiocytosis
- Sarcoidosis
- Wegener granulomatosis

Autoimmune disease
- Cogan's syndrome
- Polyarteritis nodosa
- Relapsing polychondritis
- Rheumatoid arthritis

Diseases of bone
- Paget disease
- Osteogenesis imperfecta
- Fibrous dysplasia
- Osteopetrosis

Metabolic disorders
- Mucopolysaccharidoses

Varicella-Zoster

Varicella-zoster virus (VZV) is a herpes virus that results in varicella or chickenpox with primary infection. Once the primary infection is cleared, VZV remains dormant in the dorsal root ganglia. Reactivation of the virus, often during periods of suppressed cellular immunity, results in shingles, or a dermatomal vesicular eruption. Reactivation of VZV in the geniculate ganglion results in Ramsay-Hunt syndrome, or herpes zoster oticus. Involvement of the facial nerve results in the classical presentation of deep otalgia, vesicular eruptions on the external ear and tympanic membrane, and facial palsy. Extension of the inflammatory process to involve the vestibulocochlear nerve may result in SNHL and vertigo.

Mumps and Measles

The mumps and measles viruses are members of the Paramyxoviridae family. Infection with this virus is rare in the developed world due to widespread use of vaccination, though it is still common worldwide. Mumps infection commonly presents with unilateral or bilateral parotitis and orchitis in males. The classic presentation of measles (rubeola) involves cough, coryza, conjunctivitis, white oral mucosal lesions known as Koplik spots, and a maculopapular rash. SNHL with mumps is uncommon, affecting less than 0.05% of patients, and tends to be unilateral (5). Similarly, hearing loss is uncommon in measles infection, seen in approximately 0.1% of patients.

HIV

HIV infection is associated with a significant incidence of SNHL, though this relationship is not fully understood. The etiology is likely variable and includes a high incidence of middle-ear disease, opportunistic infections and malignancies of the CNS, viral labyrinthitis and neuritis, and ototoxicity from medications used to treat HIV infection and its complications (6).

Bacterial Infection

Most bacterial infections involving the inner ear represent extension of inflammation or infection from the middle ear or CNS. Acute otitis media can produce a sterile serous labyrinthitis secondary to the passage of bacterial toxins and inflammatory mediators into the inner ear fluids, likely through the round window or a dehiscent lateral semicircular canal in patients with chronic middle-ear disease and cholesteatoma. This typically causes a mild high-frequency hearing loss. Entrance of bacteria into the inner ear will lead to a suppurative labyrinthitis, which is heralded by severe hearing loss, vertigo, and vegetative symptoms.

Similarly, in patients with meningitis, bacteria may invade the labyrinth via the internal auditory canal or the cochlear aqueduct. SNHL is a common complication of meningitis, particularly in children. Up to a third of patients with bacterial meningitis sustain some loss of hearing. The hearing loss is typically bilateral and stable, though it may be unilateral and progressive or fluctuating. Male sex, CT scan evidence of elevated intracranial pressure, nuchal rigidity, low cerebrospinal fluid (CSF) glucose levels, and *Streptococcus pneumoniae* as the infective agent all are associated with an increased incidence of postmeningitic SNHL.

Syphilis

Syphilis was historically a common cause of otologic dysfunction though this late manifestation of the disease is uncommon today in the developed world. Syphilis is caused by infection with *Treponema pallidum*, which may be transmitted transplacentally (congenital syphilis) or through sexual contact (acquired syphilis). Though the incidence of syphilis peaked in the United States in the 1940s and has since declined, there has recently been an increase in the incidence among male homosexuals and patients with HIV (7,8). Syphilis is characterized by classic symptomatic stages interspersed with periods lacking significant symptoms. Primary syphilis is typically seen in the acquired form and is characterized by the presence of a chancre (a painless, nonpurulent, and indurated ulcer

in the region of sexual contact), which usually appears 3 weeks after initial infection. Although usually solitary, multiple ulcers may be seen in HIV-infected patients (7); however, chancres may go unnoticed and may only be seen in a third of cases (9). Symptoms can last from 3 to 90 days, but often go unnoticed (10). Secondary syphilis occurs weeks after the chancre has healed and is characterized by a variety of mucosal and cutaneous lesions that appear 2 to 12 weeks after initial infection (it may overlap the primary stage in up to 75% of HIV-infected patients) as well as the presence of constitutional symptoms such as fever and malaise. Asymptomatic meningitis may occur in up to 40% of patients (10), although associated sudden progressive bilateral hearing loss and vertigo are rare (11). Other organ systems may be involved, including the liver, kidney, eyes, and joints. The latent phase follows, which is characterized by a lengthy period free of symptoms. Tertiary syphilis, which is similar to late congenital syphilis, manifests years after initial infection. It is characterized by cardiovascular, gummatous, and neurologic involvement. Approximately 15% to 40% of untreated patients will progress to the third stage (7). Neurosyphilis is composed of meningovascular and parenchymal lesions that can lead to demyelination (tabes dorsalis), motor weakness, and sensory loss.

The diagnosis of syphilis depends on clinical findings, histologic examination of lesions, and serologic testing for syphilis. The Venereal Disease Research Laboratory screening test and rapid plasma reagin are useful screening tests, but lack sufficient sensitivity for both early and late syphilis (10). Treponemal tests, such as the fluorescent treponemal antibody absorption (FTA-ABS) test or a microhemagglutination test for *T. pallidum*, have higher sensitivity and specificity, and are often required for diagnosis. In fact, routine serologic testing for otosyphilis is recommended in all cases of idiopathic progressive SNHL (12). In addition, the diagnosis of neurosyphilis may require testing of CSF (10).

The otologic manifestation of syphilis presents as both hearing and vestibular dysfunction. Sensorineural hearing is very common from both in congenital and the later stages of acquired syphilis. It can be present in up to 40% of patients with congenital syphilis and up to 80% to 90% of patients with neurosyphilis (13). In addition, many patients present with vestibular dysfunction similar to that seen with Ménière disease (14). In fact, it has been reported to be present in up to 7% on patients thought to have Ménière disease (11). Left untreated, however, otogenic syphilis has a more aggressive course than Ménière disease, commonly involving both ears and leading to profound deafness. Physical exam reveals signs consistent with SNHL and peripheral vestibular loss. Hennebert sign (vertigo and nystagmus induced with air pressure to the middle ear) and Tullio phenomenon (vertigo and nystagmus caused by loud noise) may be associated with tertiary syphilis.

The changes in the inner ear resulting from syphilis have been well described. The otic capsule may be involved during the secondary and/or tertiary stages of infection. Involvement manifests as osteitis of the otic capsule bone. Inflammation is mediated by mononuclear cells and results in patchy bone reabsorption; these spaces are subsequently filled with fatty marrow and loose connective tissue (15). It is accompanied by an obliterative endarteritis typical of syphilitic infection. In severe cases, gumma (lymphocytic infiltrates, vascular occlusion, and central necrosis) may be noted in the otic capsule. In addition, degeneration of the labyrinthine membrane, endolymphatic hydrops, and fibrosis have been described (16). The peripheral vestibular system may also be involved during the second stage of infection, in which both the VIII cranial nerve and labyrinth are involved in fulminant meningoneurolabyrinthitis.

Penicillin-based antibiotics (or an alternate if allergic) are the treatment of choice, with duration varied by stage of disease. The use of corticosteroids in the treatment of otogenic syphilis is controversial (11,17–20). The prognosis for hearing loss in otogenic syphilis is poor, with hearing improvement seen in less than one-third of treated patients (13).

Lyme Disease

SNHL has also been reported in association with infection by another spirochete, *Borrelia burgdorferi*, the causative organism of Lyme disease. The organism is introduced into the skin by the bite of an infected tick of the genus *Ixodes*. The spirochete has particular tropism to skin, CNS, heart, joints, and the eyes. It is not fully clear which features are a result of disseminated infection and which result from the systemic inflammatory response. In the head and neck, Lyme disease is most commonly associated with facial paresis, particularly in children. There have also been reports of sudden SNHL or a Ménière-like syndrome.

GRANULOMATOUS DISEASE

Langerhans Histiocytosis

Langerhans histiocytosis (previously called histiocytosis X) describes a group of idiopathic disease caused by the abnormal proliferation of histiocytes. Histiocytes, normally benign cells found in the dermis or epidermis, accumulate in the skin, bone, lymph nodes, and visceral organs. This group is comprised of three diseases, eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease, which describe progressively more aggressive and widespread manifestations of the same underlying pathology. Patients with eosinophilic granuloma develop solitary osteolytic lesions without systemic manifestations. The course of this disease is typically benign, and patients often undergo spontaneous regression of their lesions. For those who do not, local excision of the granuloma or intralesional steroids can be performed. Hand-Schüller-Christian disease typically affects patients less than 5 years old, who develop multifocal osteolytic lesions with rare

extraskeletal involvement. Up to 25% of patients present with the triad of osteolytic skull lesions, exophthalmos, and diabetes insipidus. Letter-Siwe is the most aggressive of this group, presenting most commonly in children less than 3 years old, who develop disseminated disease with diffuse involvement of multiple organs. Prognosis is poor with most patients succumbing to the disease in childhood (21). Lesional biopsy for each of these diseases demonstrates characteristic tennis racket–shaped Birbeck granule on histology, the result of cytoplasmic inclusions bodies. In addition, diagnosis can be made by demonstrating the presence of the CD1 antigen with immunohistochemistry (21).

The otologic manifestations of these diseases result from the development of a granuloma within the temporal bone. As the granuloma expands, it can cause conductive hearing loss, otorrhea, facial nerve paralysis, vertigo, and SNHL depending on which anatomic structures the granuloma violates (22,23). For patients with systemic disease and a temporal bone lesion, systemic steroids are the first line of therapy, with etoposide, vincristine, and vinblastine reserved for refractory patients. For patients with disease localized to the temporal bone, surgical debulking can be performed with topical and intralesional injection of steroids. Radiation therapy has also been successful in treating temporal bone lesions refractory to resection (24).

Sarcoidosis

Sarcoidosis is a chronic multisystem disorder characterized by the presence of noncaseating granulomas. Classically, patients present with pulmonary symptoms characterized by persistent cough and hilar lymphadenopathy on chest x-ray. In addition, they can develop a granulomatous skin rash, iridocyclitis, keratoconjunctivitis, hepatosplenomegaly, myalgias, arthralgias, and neuropathies. Laboratory examination typically demonstrates hypercalcemia and an elevated angiotensin-converting enzyme level.

The otologic manifestations of sarcoidosis can result from uveoparotid fever or granulomatous disease within the middle ear or temporal bone. Uveoparotid fever, or Heerfordt syndrome, describes the constellation of parotitis, uveitis, fever, and facial nerve paralysis (25). Temporal bone or middle-ear granulomas can result in conductive or sensorineural hearing loss and vestibular dysfunction. Primary treatment of sarcoidosis is accomplished with corticosteroids. Refractory patients can benefit from methotrexate, cyclophosphamide, and number of other immunomodulatory agents (26).

Wegener Granulomatosis

Wegener granulomatosis is a systemic vasculitis of medium and small blood vessels resulting in a triad of necrotizing granulomas of the upper airway, necrotizing glomerulonephritis, and systemic necrotizing angiitis. Though Wegener granulomatosis is due to an autoimmune process, it is included in this section on granulomatous disease given that the otologic manifestations are mostly due to granulomatous involvement of the middle ear. Necrotizing granulomas can develop within the middle ear and mastoid, compromising the ossicular chain and eustachian tube function, resulting in a conductive hearing loss. This is more common than inner ear disease, but 8% to 20% of patients with Wegener granulomatosis do develop SNHL that is likely more similar in etiology to autoimmune disease as is discussed later in this chapter (27,28).

AUTOIMMUNE DISEASE

Autoimmune inflammation of the inner ear may be part of a systemic autoimmune syndrome or may occur in isolation as an organ-specific process. The most common autoimmune diseases that affect the ear are Cogan syndrome, polyarteritis nodosa (PAN), rheumatoid arthritis, relapsing polychondritis, and Wegener granulomatosis. The clinical presentation and pathophysiology of these diseases' otologic manifestations are reviewed in this section. Several of these diseases have also been associated with cases of sudden hearing loss and histopathologic evidence of labyrinthitis (29). When autoimmune inflammation of the inner ear occurs as an organ-specific process, we refer to this as AIED, a relatively recently identified disease about which much remains unknown.

Cogan Syndrome

Cogan syndrome is a rare disease characterized by nonsyphilitic interstitial keratitis associated with vertigo, tinnitus, and hearing loss (30,31). The auditory and vestibular dysfunction resembles that seen in Ménière disease and untreated, progresses to profound deafness within weeks or months (32). The interval between ocular and otologic disease varies from a few weeks to a year; either organ may be affected first. Other forms of ocular inflammation, including uveitis, iritis, episcleritis, or conjunctivitis, may occur instead of the keratitis, in which case the disorder may be defined as atypical Cogan syndrome (33). The etiology of Cogan syndrome is unknown. While the relatively focal inflammation suggests organ-specific autoimmunity, this has not been proven. Like other vasculitides, the disease may represent a hypersensitive immune reaction to a viral infection. Vogt-Koyanagi-Harada syndrome presents with symptoms similar to those seen in Cogan syndrome. However, it also includes depigmentation of the hair and skin around the eyelashes, loss of eyelashes, and onset of aseptic meningitis. It may represent an autoimmune reaction to melanin-containing cells (34).

Polyarteritis Nodosa

Immune-mediated inner ear disease (IMIED) can also be a component of PAN (35). Postmortem temporal bone histopathologic studies on patients with PAN have

demonstrated vasculitic changes within the labyrinth. PAN is a systemic vasculitis of small and medium blood vessels without glomerulonephritis. Vessel wall inflammation progresses to aneurysmal dilation, thrombosis, and tissue infraction with the manifestations of the disease being those of end-organ ischemia. There is an association with hepatitis B infection with approximately 30% of PAN patients demonstrating positive hepatitis B surface antigen.

Relapsing Polychondritis

Relapsing polychondritis describes an immune-mediated, episodic inflammation of cartilaginous structures. This inflammation can affect any of a number of cartilaginous structure including those of the ear, nose, trachea, larynx, and ribs. As with many autoimmune disorders, women are more commonly affected than men, and the age of symptom onset is typically in the fifth decade of life. Acutely, the disease manifests as local inflammation with resulting arthropathies and can be associated with weight loss, myalgia, and fever. Over time, recurrent bouts of cartilaginous inflammation result in atrophy, scarring, and anatomic distortion of cartilaginous structures. On laboratory studies, patients present with an elevated erythrocyte sedimentation rate (ESR), normochromic normocytic anemia, and positive rheumatoid factor (36).

The otologic manifestations of relapsing polychondritis affect the cartilaginous portion of the pinna. Patients present with recurrent inflammation of the pinna, characterized by erythema, tenderness, and pain that spares the lobule and the canal (37). First-line treatment is with enteral corticosteroids. Second-line therapeutic agents include dapsone, indomethacin, and salicylates.

Rheumatoid Arthritis

Rheumatoid arthritis is another immune-mediated disease that can manifest otologic pathology. It is characterized by a persistent inflammatory synovitis resulting in progressive destruction of the cartilage within joints. Like relapsing polychondritis and many other autoimmune diseases, it is more common in women and typically presents in the fifth decade of life. Acutely, this disease causes myalgias, muscular weakness, fatigue, and anorexia. Over time, patients develop joint pain, inflammation, and deformation that are typical of the disease (38). Laboratory studies mirror those of relapsing polychondritis with elevated ESR, normochromic normocytic anemia, and positive rheumatoid factor.

The otologic manifestations of rheumatoid arthritis can affect the external, middle, and inner ear. Rheumatoid nodules, painful cutaneous or subcutaneous raised lesions, can develop on the external ear. Middle-ear manifestation is typically characterized by a conductive hearing loss secondary to involvement of the ossicular suspensory ligaments and resulting abnormal middle-ear mechanics. In addition, patients have a significantly higher rate of SNHL than the general population though the pathophysiologic mechanism for this is unknown (39). First-line treatment typically involves medical therapy with aspirin or nonsteroidal anti-inflammatory drugs, though steroids and immunosuppressant are commonly used for those with refractory or more severe disease.

Autoimmune Inner Ear Disease

AIED specifically refers to the clinical presentation of idiopathic, rapidly progressive, bilateral SNHL. This condition has come to be known by a variety of names including IMIED and immune-mediated cochlea-vestibular disease. While the pathogenesis of otologic dysfunction in some systemic autoimmune diseases has been well defined, our understanding of AIED still leaves much to be discovered.

AIED was first described by McCabe in 1979 as a rapidly progressive (over a course of weeks to months) bilateral SNHL that responds to the administration of immunosuppressants (40). In his original description, McCabe describes pathology restricted to the inner ear, which is now referred to as primary AIED. Since that time, secondary AIED has come to refer to multisystemic, organ-nonspecific autoimmune diseases that also involve the inner ear.

The classification of this disease as an autoimmune or immune-mediated disorder was initially assigned given the improvement in symptoms patients achieved with immunosuppressive therapy. Autoimmune diseases result when the immune system's ability to distinguish between self and non-self is disturbed, and cytotoxic mechanisms designed to destroy foreign material and microorganisms attack the native tissue. This process is mediated by a specific antigen inherent to the targeted organ to which the immune system has become improperly sensitized. Confirming the presence of this antigen confirms the immune-mediated nature of disease and helps guide treatment. As is discussed, a large amount of research has been dedicated toward identifying such an antigen for AIED, with limited success. Despite this, AIED is still felt to most likely arise from autoimmune etiology.

Epidemiology

Primary AIED is very rare, though it is difficult to determine the exact incidence, given the lack of a definitive diagnostic test to identify affected patients. Retrospective studies estimate the incidence as less than that of sudden SNHL, which occurs with an incidence of 1 case per 5,000 to 10,000 population per year (34,41).

Pathophysiology

The pathogenesis of AIED has been the subject of extensive research guided by the goal of developing more effective therapies. Given the probable immune-mediated nature of this disorder, much of this research has focused on identifying the responsible target antigen within the inner ear that

is provoking the immune response. The main contribution of this work pertains to the detection of a specific antibody that binds to a 68-kilodalton (kDa) bovine inner ear antigen on Western blot analysis. This antibody has been found in the guinea pig model, as well as in humans with AIED (42,43). The same antibody was also found to bind to the inducible form of bovine (but not human) heat shock protein 70 (HSP-70), and as a result, this protein was once considered integral to the pathogenesis of AIED. More recent data suggest that the antibody targets multiple peptides similar to those present in the highly conserved protein CTL2, which is abundantly expressed in both the guinea pig and human inner ear (44). CTL2 coprecipitates with the protein cochlin, which is one of the most expressed proteins in the inner ear. Cochlin is critical to the structure and function of the inner ear, and mutations are known to cause cochleovestibular pathology. Recent work reveals that cochlin-specific serum Ab titers are significantly elevated in those with AIED in comparison to age-matched controls (45). The same study also implicates T-cell response to this specific protein, supporting cochlin as a possible target antigen susceptible to both B-cell and T-cell influence. CTL2 and cochlin have therefore replaced HSP-70 as the most likely target of the immune target in AIED.

Clinical Presentation

The hallmark of AIED, as originally described by McCabe, is the presence of bilateral SNHL that progresses during a period of weeks to months (34). It is important to note that the hearing loss may initially be unilateral and that it may take months for the bilaterality to emerge. Fluctuations in hearing may occur, but the overall course is one of a relentless deterioration in auditory function. Approximately 50% of patients have symptoms of vestibular dysfunction, with 20% of patients experiencing episodes of vertigo consistent with those seen in Ménière disease (34).

Differential Diagnosis

Critical in the diagnosis of AIED is differentiating it from sudden idiopathic SNHL, as these two diseases can present with similar symptoms. However, AIED and idiopathic sudden SNHL are two distinct disorders. AIED is considerably more rare than sudden SNHL. AIED is by definition bilateral, while sudden hearing loss is virtually always unilateral, although, at initial presentation, AIED may not have yet affected both ears. Sudden hearing loss develops in less than 72 hours. In contrast, AIED progresses over days to months such that serial audiograms on a monthly basis will show continued decline. Sudden hearing loss is an otologic emergency with a treatment window of perhaps 2 to 4 weeks, during which a short burst and taper of corticosteroids are recommended to achieve optimal recovery.

AIED is not urgent. Patients with progression of hearing loss over a 6- to 12-month period can still achieve significant recovery with administration of a long course of high-dose corticosteroids or other immunosuppressive drugs. Throughout the otolaryngology community, there is general awareness that some cases of SNHL are potentially reversible with corticosteroids. However, there is little awareness that these two entities are quite different in etiology, presentation, workup, and management.

The clinical presentation of AIED may closely mimic that of Ménière disease. In fact, during the first months of evaluation, the two entities may be difficult to differentiate. Both can manifest fluctuations in hearing and episodic vertigo. If corticosteroids are administered, a spontaneous recovery in hearing, as seen in Ménière disease, may be mistaken for a positive response to immunosuppressive therapy. Ultimately, the more aggressive course of AIED will allow for the differentiation of these two disorders. It has been suggested that a subgroup of patients with symptoms of Ménière disease may share a common pathophysiology with patients who have AIED. This association is based on studies that have noted that approximately one-third of patients with Ménière disease may have a positive Western blot assay for anti-HSP-70 antibodies (46,47). However, this finding was not supported by a later study, in which the commercially available assay was utilized (48).

Otosyphilis can closely mimic AIED, and must be ruled out as part of the workup. An acoustic neuroma may present with sudden or progressive unilateral SNHL. Rarely, meningitis, multiple sclerosis, or malignancy (e.g., metastatic disease, lymphoma) involving the dura may manifest as rapidly progressive bilateral hearing loss.

Diagnosis

No definitive diagnostic test exists to confirm a diagnosis of primary or secondary AIED, and identification of the disease still relies on history of clinical exam. In addition, an appropriate review of systems should include questions pertaining to recurrent or chronic ocular disease, nephritis, arthritis, pneumonitis, sinusitis, and inflammatory bowel disease in order to differentiate between primary AIED and secondary AIED.

Despite this clinical diagnosis, a number of routine serologic tests should be ordered in patients who may have suspected AIED in order to rule out other causes of otologic dysfunction. These include a complete blood count with differential white count, ESR, rheumatoid factor, antinuclear antibody test, anti–double-stranded DNA antibodies, anti-SSA/B antibodies, antiphospholipid antibodies, C3 and C4 complement levels, anti-gliadin antibodies, and Raji cell assay for circulating immune complexes. An FTA-ABS test (or a *T. pallidum* hemagglutination test) must be obtained to rule out otosyphilis. An HIV test may be considered to rule out AIDS-associated hearing loss. An MRI with paramagnetic enhancement must be obtained to rule out the retrocochlear lesions discussed earlier in this chapter.

Though not yet clinically applicable, a number of immunologic assays have been proposed to diagnose AIED. Tests of cellular immunity have been advocated by McCabe (lymphocyte migration inhibition assay) and Hughes

(lymphocyte transformation test) (49). Unfortunately, these tests have never been adequately validated, and their diagnostic accuracy has not been determined. During the 1990s, attention was focused on the role of Western blotting for detection of an antibody that binds to a 68-kDa antigen derived from bovine temporal bone extract and to the inducible form of HSP-70 (50–52). As noted earlier in this chapter, these antibodies were first determined to be of significance when they were detected in both guinea pigs immunized with bovine inner ear extract and in humans manifesting AIED (52). In a prospective controlled study, with well-defined entry criteria, Moscicki and his colleagues demonstrated that 89% of patients with active, rapidly progressive hearing loss did have detectable levels of this antibody, while none of the control patients had positive Western blots (53).

There have been recent studies evaluating the use of PET scan as a tool for the diagnosis of AIED. Although initial observations suggested an association between AIED and positive PET scans, the most recent work fails to show any diagnostic benefit to PET scan (54). At this time, there is no role for PET in diagnosis of AIED.

In summary, the diagnosis of primary AIED is based on clinical evaluation, the demonstration of progressive SNHL on audiometric assessment done at monthly intervals, and most importantly, a positive response to the administration of corticosteroids. The presence of a positive Western blot may support the diagnosis of AIED but, in and of itself, can neither confirm nor rule out the diagnosis.

Treatment

Corticosteroid therapy for AIED evolved during the mid-1980s through the 1990s as a result of clinical experience. Niparko et al. (55) reported a prospective, randomized trial that showed a majority of patients with suspected AIED responded to corticosteroids, although the response was highly variable. These data seem to substantiate the current practice of most otologists. Initial therapy for adults consists of a therapeutic trial of prednisone (60 mg daily for 4 weeks). Pediatric patients receive 1 mg/kg/d of prednisone for 4 weeks. Although patients may occasionally respond early in the 4-week period, many do not begin to improve until late in the month; shorter courses of treatment usually result in relapse.

Patients' hearing is tested at the initiation of therapy and again at 4 weeks. If the threshold has improved by ≥15 dB at one frequency or 10 dB at two or more consecutive frequencies, or if the discrimination is significantly improved, patients are considered steroid responders. Nonresponders are tapered off their medication in 12 days. Responders continue full-dose therapy until monthly audiograms confirm that they have reached a plateau of recovery. Their medication is then slowly tapered over 8 weeks to a maintenance dose of 10 to 20 mg every other day. This maintenance dose is continued for a variable time. Clinical observation suggests that patients with a treatment duration of fewer than 6 months are at increased risk of relapse compared with those treated for 6 months or longer.

Patterns of response to corticosteroid therapy vary. Some patients have improvement in threshold, some in discrimination only, and some in both areas. Some patients with hearing loss fluctuation and progression before therapy show stabilization in their hearing without actual improvement. Historically, these cases have been considered nonresponders, but this issue is currently under reassessment. The majority of responders slowly taper off the steroid dose, wean from steroids, and do well. A subset of AIED patients relapse while tapering or after discontinuing steroids. In some instances, additional corticosteroid therapy is effective. In such cases, alternative immunosuppressive drugs are considered. Some patients, especially in the pediatric age group, may occasionally show steroid-dependent hearing loss. In other words, they cannot be weaned below a certain level of steroid dosage without decline in hearing. Such patients often develop unacceptable side effects of chronic steroid administration. Methotrexate has been used as part of a prednisone-sparing regimen; however, a recent randomized, prospective controlled, multicenter trial has shown methotrexate to be no better than a placebo at maintaining a remission in these patients (56).

Corticosteroid therapy has obvious limitations. Long-term administration carries a significant risk for gastritis and ulcers, fluid retention and weight gain, blood pressure lability, altered blood sugar metabolism and diabetes, avascular necrosis of the hip, mood changes or psychiatric problems, sleep disturbance, accelerated cataract formation, osteoporosis, and cushingoid habitus. Overall steroid response rate is approximately 60% in AIED patients, and patients with vestibular symptoms appear to be particularly sensitive (57). Recent research demonstrates that corticosteroid nonresponders have elevated plasma level of IL-1B and MMP-9 as compared with clinically responsive patients, suggesting that IL-1B blockade may be viable therapy for these patients (58). Although high-dose corticosteroids are associated with serious side effects, with appropriate patient selection, monitoring, and patient education, high-dose corticosteroids are safe and effective (59).

A number of alternatives to systemic corticosteroids have been proposed, including methotrexate, etanercept, and cyclophosphamide. Low-dose methotrexate appeared to be useful as an adjunct in management of steroid-dependent hearing loss (60). However, as noted earlier in this chapter, the recent large trial indicates that it may not serve an effective role as a prednisone-sparing drug. Etanercept, an inhibitor of tumor necrosis factor (TNF) alpha, has recently been used to treat AIED. Anecdotally, it appears to work well in combination with methotrexate because of its steroid-sparing effect. As seen in rheumatoid arthritis, etanercept alone does not appear nearly as effective. In both an open-label and blinded, prospective study, etanercept was shown not to be efficacious in improving hearing loss in patients with AIED (61–63).

Cyclophosphamide is a potent cytotoxic agent generally used for cancer chemotherapy and treatment of Wegener granulomatosis. Although some advocate its use as a first-line drug, the high risk of toxicity makes it a better choice as a salvage drug or treatment of last resort (64). An initial dose of 1 mg/kg/d orally for 4 to 6 weeks may be instituted. When no response is apparent, the dose is doubled to 2 mg/kg/d. Responders are treated for 6 to 12 months. Toxicity includes severe myelosuppression, opportunistic infection, hair loss, cystitis, infertility, and increased risk of malignancies. Weekly monitoring of hematologic status is mandatory. Many patients, when confronted with the risk of this medication, would rather consider cochlear implantation.

Intratympanic steroid therapy, intratympanic TNF alpha inhibitor, systemic immunoglobulin G injections, and plasmapheresis are possible treatments with sound theoretical justification (65,66). Intratympanic steroid therapy is particularly appealing because it is minimally invasive and enables direct application of the drug to the affected site with low risk of systemic effects (67). There are, however, no published series in which these treatments have been systematically applied. The best role for any of these treatment modalities remains to be determined.

Recently, researches have experimented with immunotherapy as a means of treating AIED. Studies have demonstrated that a low dose of beta-tubulin is active orally in an antigen-specific fashion and capable of inhibiting the autoimmune reactions in the inner ear by suppressing Th1 (IFN-gamma) and increasing Th2 and Th3 (IL-4, IL-5, IL-13, and TGF-beta) cytokines. Oral antigen tolerance may in the future be used to treat AIED (68).

In summary, the only drugs of proven utility in the management of AIED are the corticosteroids. All other immunosuppressants currently employed have not been systematically evaluated and carry with them serious toxicity risks. In a patient who cannot be maintained on corticosteroids because of complications, the possibility of withdrawing treatment, with the intention of inserting a cochlear implant when the hearing becomes significantly impaired, must be considered.

DISEASES OF BONE

Paget Disease

Paget disease, also known as osteitis deformans, is a chronic progressive disorder of bone metabolism of unknown etiology. It results from increased activity of osteoclasts and osteoblasts, which manifest as bony hypertrophy and remodeling. Its prevalence increases dramatically with age, with 3% of people over the age of 40 demonstrating histopathologic evidence of the disease and 11% of people over the age of 80 demonstrating histopathologic evidence of the disease (69). The disease is far more common among men than women with relative incidence of about 4:1. Patients with Paget disease typically present in their sixth decade, most commonly with complaints of an enlarging skull, progressive kyphosis, and deformities of the pelvis, femurs, and tibia. Radiologic findings for these patients include thickening of the calvarium with ill-defined densities and poor definition of cortical margins of the inner ear and internal auditory meatus.

The otologic manifestations of Paget's typically present as a mixed conductive and SNHL, estimated to effect between 5% and 44% of patients (70). The conductive portion of this hearing loss is typically down-sloping and 20 to 30 dB in severity. The etiology of this hearing loss is not well explained and cannot be attributed to compressive etiologies as with other diseases of bone. It is believed to arise primarily from changes in bone density and geometry that interfere with normal hearing mechanisms. In addition, patients with Paget can present with tinnitus and mild vestibular complaints. Facial nerve symptoms are highly unusual.

Treatment of Paget disease relies primarily on bisphosphonate therapy, which inhibits osteoclast activity, thereby inhibiting bone reabsorption. Calcitonin has also been demonstrated to be effective in this manner. There are no surgical treatments to improve conductive hearing loss for these patients.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI), also known as Hoeve-de Kleyn syndrome, is a connective tissue disorder that manifests as a variety of types with vastly differing severity. It results from mutations in either of two genes codes for type I collagen (COL1A1 and COL1A2) (71).

Type I OI is the mildest form of the disease and is inherited in an autosomal dominant pattern. This is the classic form of the disease and is the most common type, with an incidence of 1:30,000. Clinically, patients demonstrate characteristic blue sclera and nondeforming fractures while maintaining normal stature. Type II OI is lethal with patients developing multiple fractures *in utero*, often resulting in stillbirth. It is inherited in an autosomal recessive pattern and has an incidence about half that of type I, 1:60,000. Type III and type IV are increasingly rare and manifest with a severity intermediate to that of type I and type II. Patients with type III OI develop multiple fractures with resulting progressive bone deformity. They also demonstrate blue sclera at a young age but this transitions to a normal white sclera later in life. This type can be inherited in an autosomal recessive or dominant pattern. Type IV OI presents with a similar clinical picture to type I but with normal, white sclera. Like type I OI, clinical manifestations can be mild, and a patient's disease can elude clinical detection.

It is estimated that 30% to 50% of patient with type I OI develop hearing loss, 50% of patients with type II OI develop hearing loss, and 10% to 30% of patient with type IV OI develop hearing loss (72). There is no demonstrated association between the severity of peripheral fractures and the presence of hearing loss. Conductive hearing loss results from fractures to the ossicles, most commonly the long process of the incus or the stapes crura. This conductive hearing

loss has been addressed successfully with amplification or ossiculoplasty to replace fractured ossicles. In addition, stapedectomy can be effective but must be performed very delicately due to the fragility of the ossicles. There is some evidence to demonstrate that stapedectomy outcomes are better when performed for type I OI (73).

Fibrous Dysplasia

Fibrous dysplasia is a benign, chronic, slowly progressive disease of unknown etiology. It describes the replacement of normal cancellous bone by spicules of woven bone in a fibrous stroma. Fibrous dysplasia occurs in several forms: monostotic, polyostotic, or as part of the constellation of symptoms comprising McCune-Albright syndrome. The monostotic form is the most common. It usually presents late in childhood and then can become quiescent at puberty. The affected bone is most commonly a rib, the skull, the proximal femur, or the tibia. The polyostotic form usually presents earlier and will continue to progress throughout life (74). Skeletal lesions are multiple but usually unilateral. Radiologic findings typical of fibrous dysplasia include radiolucent areas with a well-defined smooth or scalloped edge and a ground-glass appearance.

Otologic manifestations of the disease manifest from craniofacial involvement, which occurs far more commonly in the polyostotic (50% to 100%) form than in the monostotic form (10% to 30%). Conductive hearing loss is the most common clinical manifestation, resulting from occlusion of the external auditory canal (EAC) due to painless, progressive involvement of the temporal bone. In addition, patients can develop a canal cholesteatoma or involvement of the ossicular chain (75). Facial nerve paralysis or paresis and SNHL have also been reported. Patients can benefit from medical treatment with bisphosphonates. Surgical treatment with canaloplasty, meatoplasty, or cholesteatoma resection can also benefit these patients.

Osteopetrosis

Osteopetrosis is a rare, inherited disorder of bone remodeling that results in characteristic increased bone density due to defective function of the osteoclasts. It presents in two forms, an autosomal recessive form and an autosomal dominant form. The autosomal recessive type, also called malignant osteopetrosis, is the more severe form. It is rapidly progressive, resulting in encroachment of the bone marrow and neural foramina. Patients consequently develop thrombocytopenia, hepatosplenomegaly, and cranial nerve palsies that often result in death (76). The autosomal dominant form, also known as Albers-Schönberg disease and marble bone disease, is more progressive, more indolent, and more common. It results in progressive head and mandible enlargement with clubbing of the long bones. Patients can also develop cranial neuropathies secondary to compression at neural foramina.

Otologic manifestations include SNHL from compression of the cochlear nerve and conductive hearing loss from thickening of the ossicles and the meso- and epitympanum (77). Facial nerve weakness can also develop from compression at the stylomastoid foramen. The only treatment for malignant osteopetrosis is bone marrow transplantation. Cochlear nerve decompression has also been described for SNHL resulting from the milder form of the disease.

METABOLIC DISORDERS

Mucopolysaccharidoses

Mucopolysaccharidoses are a group of diseases that result from inherited deficiencies in lysosomal enzymes needed to break down mucopolysaccharides. This results in intracellular accumulation of mucopolysaccharides and abnormally large dysfunctional cells with vacuolated cytoplasm. There have been 10 identified lysosomal enzyme deficiencies that make up this group. Examples of these include Hunter syndrome, an X-linked disease caused by an absence of L-iduronidase; Hurler syndrome, an autosomal recessive disease caused by a lack of iduronate-2-sulfate; and Morquio syndrome, caused by a lack of *N*-acetylgalactosamine-6-sulfate or beta-galactosidase. Diagnosis of each is made through assays that test for the presence of each of these enzymes.

The otologic manifestation of mucopolysaccharidoses typically presents as a mixed hearing loss. The conductive component is usually secondary to eustachian tube dysfunction and resulting serous otitis media. The cause of SNHL is unclear though it is thought that abnormal lipid metabolism within nerve cells may be at fault. Treatment of these patients is typically supportive with long-term tympanostomy tube placement to alleviate serous otitis media (78). Some patients respond to systemic enzyme replacement therapy. Current research is investigating the efficacy of gene therapy for these patients (79).

HIGHLIGHTS

- Infectious diseases are the most common systemic diseases to manifest otologic pathology.
- Congenital CMV infection can result in both a severe SNHL in babies presenting with symptomatic infections and a variable progressive SNHL in children with asymptomatic infections.
- Up to a third of patients with bacterial meningitis sustain some SNHL, which is typically bilateral and stable, though it may be unilateral and progressive or fluctuating.
- Otogenic syphilis can mimic Ménière disease, though it typically has a more aggressive course, involving both ears and leading to profound deafness.

- Langerhans histiocytosis can present as an isolated granuloma affecting the temporal bone (eosinophilic granuloma) or as a multifocal (Hand-Schüller-Christian disease) or disseminated (Letterer-Siwe disease) process.
- Granulomatous diseases most commonly cause conductive hearing losses, by disrupting the conductive mechanisms within the middle ear.
- AIED is a rare entity characterized by bilateral SNHL that progresses over weeks to months and is responsive to steroids.
- Diagnosis of AIED relies on clinical evaluation as well as a comprehensive assessment of immunologic markers; Western blot for an antibody to a 68-kDa protein that binds HSP-70 is not standard of care in the evaluation of AIED.
- Treatment of AIED is not urgent as there is a 6- to 12-month period in which a significant recovery of hearing loss is possible with administration of high-dose corticosteroids.
- Initial therapy for AIED is 60 mg of prednisone a day for 4 weeks. Response to steroids is variable, and treatment is tailored to initial response.
- Neither etanercept nor methotrexate has been shown to be efficacious in improving hearing loss in patients with AIED.
- Disease of bone can cause both conductive hearing loss by directly damaging the middle ear and ossicles and SNHL through compression of the cochlear nerve.
- The otologic manifestation of mucopolysaccharidoses typically presents as a mixed hearing loss, with the conductive component usually secondary to serous otitis media.

157 Noise-Induced Hearing Loss

Robert A. Dobie

Noise and aging are responsible for most cases of permanent hearing loss in the United States. Although not correctable by medical or surgical treatment, noise-induced hearing loss (NIHL) is preventable.

Otolaryngologists see patients with NIHL in many different contexts. A noise-exposed worker may be referred for preemployment examination, for evaluation of threshold shifts or other abnormalities detected by a hearing conservation program (HCP) at work, or for examination for compensation purposes at the end of his or her career. The otolaryngologist is expected to verify the existence and severity of the hearing loss, to render a differential diagnosis, to recommend treatment and rehabilitation, to counsel the worker, and to report to referring parties. Otolaryngologists also may be called on as consultants by employers designing HCPs or by attorneys involved in medicolegal and compensation disputes.

Patients with NIHL are also seen through the normal pathways of self-referral or physician referral. These patients often have occupational or nonoccupational exposures that are uncontrolled, and then the otolaryngologist's duty is to provide at least the rudiments of an HCP: periodic audiometry and counseling, including discussion of hearing protection. Unfortunately, most people with NIHL do not see otolaryngologists; thus, we should encourage primary care physicians either to refer noise-exposed patients or to provide these services themselves (1).

The goal of this chapter is to provide the otolaryngologist with most of the information needed to meet these needs.

PATHOGENESIS

Pure-Tone Threshold Shifts

Temporary Threshold Shifts

Exposure to loud noise for seconds to hours may cause a temporary sensorineural hearing loss that recovers almost completely within 24 hours. The magnitude of this temporary threshold shift (TTS) can be predicted from the acoustic parameters of the noise: its intensity, spectrum (frequency content), and temporal pattern. Obviously, more intense sounds lead to larger shifts. Pure tones cause TTSs that are greatest at and slightly above the frequencies of the exposure tones. As might be expected, the frequencies that we hear best are also the frequencies most susceptible to TTS. (See Chapter 141 for a discussion of the effects of middle-ear mechanics and ear canal resonance on thresholds for different frequencies.) Because high-frequency sounds (e.g., a 4-kHz tone) are usually more hazardous than low-frequency sounds (e.g., a 500-Hz tone) of the same intensity, risk cannot be predicted from measurements of decibel sound pressure level (dB SPL) alone. To avoid the cumbersome necessity of assessing risk separately for each of several octave bands of noise, there is an international consensus that estimates of hazard for NIHL should be based on measurements of decibels on the A scale (dBA), which gives greater weight to those frequencies most hazardous to human hearing (1 to 5 kHz) and lesser weight to higher and lower frequencies.

The effect of temporal pattern is more complex. Up to a point, longer exposures lead to increased TTS, but interrupted exposures cause less TTS than continuous exposures with the same overall duration. Presumably, recovery takes place during the rest intervals.

Permanent Threshold Shift

After repeated exposures to noises that initially cause only TTS, a worker may experience threshold changes that do not recover. This is called noise-induced permanent threshold shift (NIPTS). In a typical field study, a researcher determines the NIPTS attributable to 10 years' exposure at 100 dBA, for example, by measuring the hearing threshold levels (HTLs) of a group of workers so exposed and then subtracting the amount of hearing loss to be expected on the basis of aging. The amount of NIPTS and the frequencies involved depend primarily on the acoustic parameters

of the noise, as described previously for TTS. As with TTS, intermittency has a protective effect, especially for low-frequency NIPTS (2,3).

The consensus of most experts (4,5) is that NIPTS does not progress after cessation of the offending exposure. To be precise, as people with NIPTS from a prior exposure grow older, their hearing loss does not progress more rapidly than hearing loss in people who have not been noise exposed. That consensus view has been challenged recently. Noise-exposed mice may show hearing loss that progresses more rapidly than expected after the noise stops, but this phenomenon has only been demonstrated for a single inbred strain exposed as juveniles (6). A review of serial audiograms from the Framingham Heart Study showed that middle-aged men who had 4-kHz notches (presumably due to noise exposure in most cases) experienced more threshold shift at 2 kHz in subsequent years than men whose audiograms were not notched (7). Unfortunately, there was no documentation that the men with audiometric notches had actually been noise exposed (or that those without notches had not). In addition, many if not most of these men were below retirement age at the times of their initial audiograms, and there was no documentation that their occupational and nonoccupational noise exposures (if any) had ceased. A subsequent longitudinal study from South Carolina showed no difference in age-related progression of hearing loss between retirees who had had noisy careers and those who had had quiet careers (8), in agreement with the expert consensus.

Although the acoustic reflex (contraction of the stapedius muscle in response to loud sound) evolved before firearms and industrial noise, it is probably protective against NIPTS, at least for frequencies below 2 kHz, where the acoustic reflex effectively attenuates sound. Borg et al. (9) have shown in experimental animals and in humans with Bell palsy that permanent threshold shift (PTS) and TTS increase dramatically for lower frequencies when the reflex is inactivated. The efferent innervation of the outer hair cells probably exerts a protective role as well; at least in mice and guinea pigs, strong efferent olivocochlear function is correlated with resistance to NIHL (10,11).

We have already mentioned several explanations for the familiar 4-kHz notch (which can also be at 3 or 6 kHz): the greater sensitivity of the human ear to frequencies between 1 and 5 kHz, the protective effect of the acoustic reflex below 2 kHz, and the fact that intermittency is most protective for low frequencies. Recently, another reason has been added: Outer hair cells at the base of the cochlea are especially susceptible to oxidative stress (12). However, a notch is not proof of NIHL and can be seen after head injury, after barotrauma, or even in the absence of any explanatory history (13).

In both TTS and PTS experiments in animals, the amount of threshold shift caused by a particular exposure can often be reduced by adding prior exposure at lower

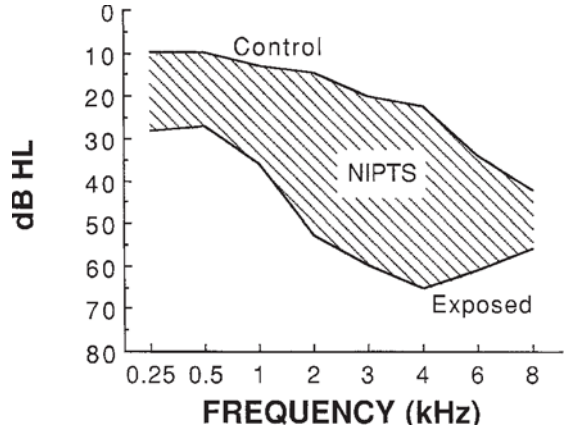

Figure 157.1 Median audiograms of retired jute weavers (exposed) and non–noise-exposed women of similar ages (control). NIPTS is estimated by subtracting HTLs expected with aging from HTLs in the exposed group.

levels; this is called "toughening" or "conditioning" the ear (14). Clearly, inner ear injury and hearing loss are not simply related to the total amount of sound energy entering the ear.

A landmark cross-sectional study of the evolution of NIHL over a working career was reported by Taylor et al. (15), in a jute-weaving factory in which noise levels (over 100 dBA) had probably been constant for generations. Figure 157.1 shows the pattern of hearing loss found in retired female weavers compared with that of age-matched female controls who had had no hazardous occupational or nonoccupational noise exposure. The shaded area indicates the estimated median NIPTS; the greatest change was at 4 kHz. Figure 157.2 shows median NIPTS curves for varying lengths of employment in the mills. As many other studies have shown, when workers are exposed to typical broad-spectrum industrial noise, the earliest changes are in the high frequencies (3 to 6 kHz). After about 10 years, loss in the high frequencies tends to plateau, but the loss continues to broaden gradually into lower frequencies.

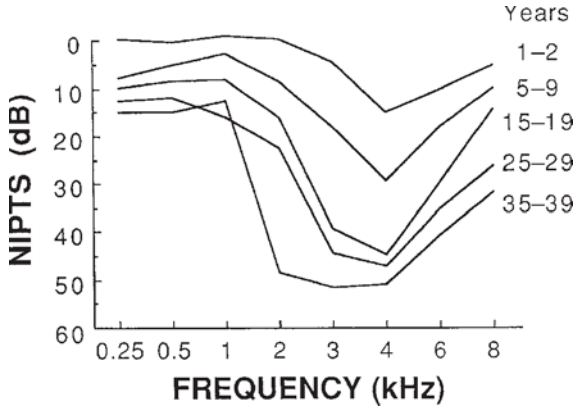

Figure 157.2 Median NIPTS as a function of audiometric frequency for different durations of exposure in jute-weaving mills (at level above 100 dBA).

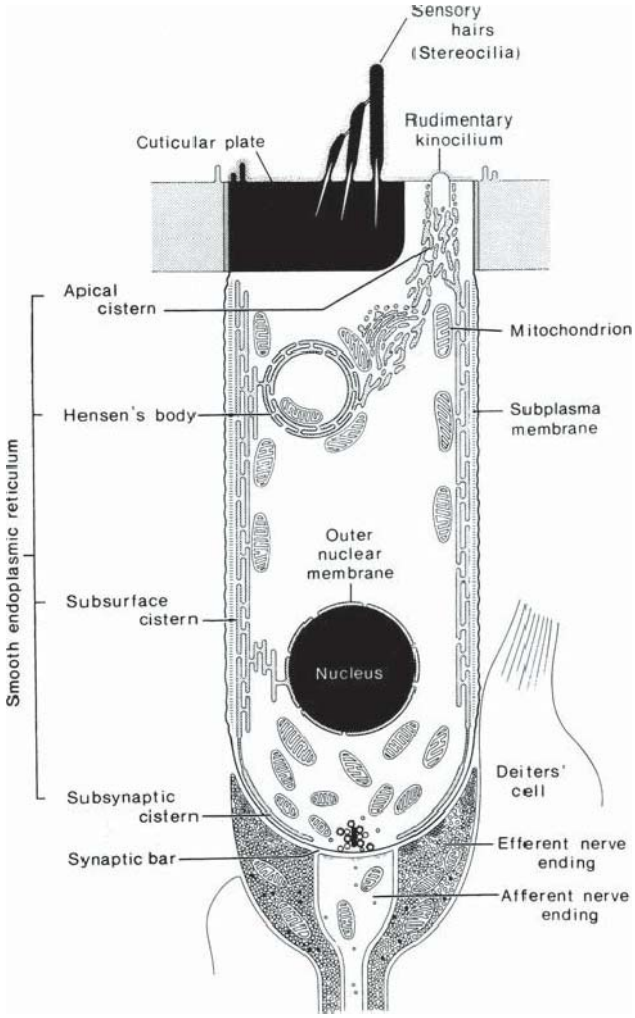

Figure 157.3 Diagrammatic cross section of a normal cochlea hair cell. (Redrawn after Lim DJ. Functional structure of the organ of Corti: a review. *Hear Res* 1986;22:117, with permission.)

Pathology

Animal studies show clearly that NIHL involves the organ of Corti, especially the hair cells (Fig. 157.3). Although almost all cell types may be affected, the outer hair cells are most susceptible to damage. It has been difficult to find anatomic correlates to TTS, but it appears that the stereocilia of the outer hair cells become less stiff and therefore respond poorly to stimulation. These floppy stereocilia may recover their normal mechanical properties and function normally again. With increasing intensity and duration of exposure sufficient to cause NIPTS, more severe damage is seen with fusion of adjacent stereocilia and loss of stereocilia. The primary site of injury appears to be the rootlets that connect the stereocilia with the top of the hair cell (16). As stereocilia are lost, the hair cells themselves may die. As the severity of exposure increases, inner hair cells and supporting cells in the organ of Corti may be damaged (Fig. 157.4), and with severe hair cell loss, secondary neural degeneration is reflected in the auditory nerve and brainstem auditory nuclei. Rapid primary degeneration of VIII nerve synapses, followed by gradual loss of ganglion cells, may also occur, probably caused by glutamate excitotoxicity (17).

Acoustic Trauma

A single exposure to a very intense short-duration sound can cause a permanent hearing loss not preceded by TTS. It is generally believed that in these instances sound mechanically damages the organ of Corti, tearing membranes, rupturing cells, and allowing perilymph and endolymph to mix. This is contrasted to the gradual loss of stereocilia and hair cells seen in NIHL, preceded by TTS, and usually considered to involve both injury and metabolic repair processes. Acoustic trauma can produce losses that are more severe than those seen with NIHL, especially in the low frequencies. At extreme levels, such as with explosive or blast injury, even tympanic membrane or ossicular injury can occur, causing conductive or mixed hearing loss.

An important type of exposure that can create either NIHL or acoustic trauma is impulse noise (18). Impulses in the range of 0.2-millisecond duration have peak energy at 2 to 3 kHz, are therefore especially hazardous to human hearing, and are typical of small arms gunfire. Such impulses, when above a critical level of 140 decibels (dB) (peak), are considered potentially hazardous to human hearing (19).

Many industrial environments contain large amounts of impact noise, usually caused by collision of metal objects. These noises have high peaks and are often reverberant as well. Intense impact noises can cause acoustic trauma, but they are less likely than impulse noises to reach critical levels.

The levels at which continuous noise and tones (in contrast to impulses and impacts) cause acoustic trauma are not well defined. The earliest cordless telephones rang through the earpiece; if the person answering the phone failed to switch manually from "ring" to "talk" mode, the phone would ring directly into the ear with a 750- to 800-Hz tone at about 140 dB SPL. Dozens of cases of permanent hearing loss occurred from single-ring exposures, each probably less than 1 second in duration. At the other extreme, single 4-hour exposures below 110 dBA probably pose negligible risk of acoustic trauma (20).

Interactions

Aging

The nature of the interaction between NIPTS and age-related hearing changes has been the subject of considerable debate. Epidemiologic studies, such as those illustrated in Figure 157.2, usually assume additivity; that is, the net hearing loss is the decibel sum of the threshold shifts from aging and from noise. When this question has been addressed explicitly, the bulk of evidence favors simple additivity. For example, Macrae (21) showed that

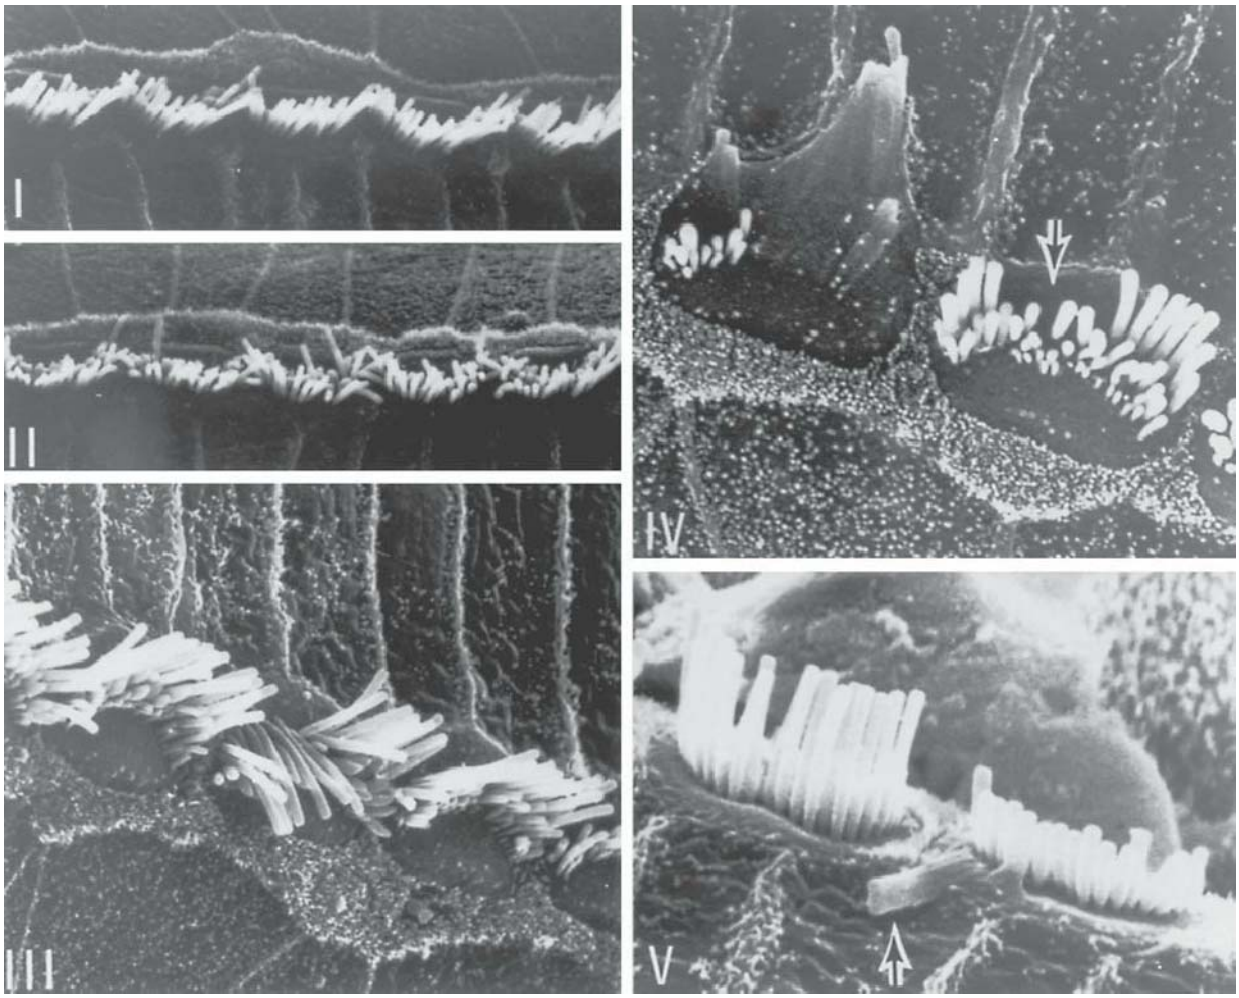

Figure 157.4 Scanning electron micrographs of cat inner hair cells that have been damaged by noise. (Redrawn after Liberman MC, Mulroy M. Acute and chronic effects of acoustic trauma: cochlear pathology and auditory nerve physiology. In: Hamernik RP, Henderson D, Salvi R, eds. *New perspectives on noise-induced hearing loss.* New York: Raven, 1982:122, with permission.)

war veterans with NIHL developed about the expected amount of additional hearing loss, based on studies of age-related hearing loss, over the ensuing years. The American National Standards Institute (ANSI) supports the theory of additivity, with a small correction factor to be used when the total hearing loss exceeds 40 dB hearing loss (22). Recent federal audiometric surveys, like those in earlier decades, show that age-related hearing loss disproportionately affects higher frequencies, especially in men; varies markedly across individuals; and accelerates in middle age (23,24).

Vibration

Czanto and Ligia (25) are among those who have shown that workers who use vibrating handheld tools, such as pneumatic hammers, grinders, and chipping tools, and who develop "vibration-induced white finger" also develop excessive NIHL. This could mean that vibration interacts with noise to damage the ear or that people who are susceptible to white finger (a peripheral vascular disorder) are also susceptible to NIHL.

Drugs and Chemicals

Humes (26) reviewed many studies and concluded that no substantial risk of hearing loss occurs from combining a noise exposure and an aminoglycoside drug when neither is present in sufficient amount to cause hearing loss on its own. Naturally, one would be reluctant to combine ototoxic drugs (primarily aminoglycosides and platinum-based antineoplastics) with hazardous noise exposures, but, with the probable exception of the newborn nursery where some borderline noise levels have been recorded, this is not a practical problem. The ototoxic drug most likely to be combined with industrial noise exposure is aspirin, but this causes a reversible hearing loss and has not been shown to potentiate or interact with NIHL.

Carbon monoxide (CO), xylene, styrene, and toluene have been reported to cause sensorineural hearing loss in rats. Workers exposed to toluene or xylene in addition to noise developed more hearing loss than those exposed to noise alone (27,28). Exposures in many of these studies were undocumented or were above Occupational Safety and Health Administration (OSHA) permissible time-weighted

average (TWA) exposures, raising the question of whether exposures below OSHA limits could cause hearing loss, either alone or by interacting with occupational noise. One study (29) showed that styrene exposure below currently recommended values, plus noise, was associated with more hearing loss than noise exposure alone. Another showed that mixed solvent exposures, almost all below OSHA permissible levels, were associated with slightly elevated progression of high-frequency hearing loss (30).

Susceptibility

Persons vary widely in the degree of TTS or PTS caused by noise exposures. Efforts to predict, measure, or explain these differences in susceptibility have generally been fruitless in humans. Men often display more hearing loss in noisy occupations than do women, but this may be due to different nonoccupational exposures (especially shooting) between the genders. Mice inherit susceptibility to both NIHL and age-related hearing loss (31,32); genetic tests (33) or tests of efferent function (10) may someday permit prediction of human susceptibility to NIHL. In most experimental animals, there is a critical period in infancy, about the time of final maturation and innervation of the hair cells, in which susceptibility to NIHL is greater than at other times (34). Whether this happens in human infants is unclear.

Otoacoustic emissions (OAEs) are predictably reduced or absent in NIHL. In military studies of young men with excellent pre-noise hearing thresholds, those with baseline-reduced OAE amplitudes (of unknown etiology) were more likely to experience substantial pure-tone threshold shifts after either continuous (35) or impulsive (36) noise exposure. However, *changes* in OAE amplitude have not been shown to predict—or even to correlate with—audiometric threshold shifts.

Pathophysiology and Pathogenesis

Many investigators have wondered whether there was a vascular component to NIHL, but evidence has been conflicting. Cochlear blood flow has been shown to increase or decrease for long noise exposures, and it is unclear whether vascular disease increases susceptibility to NIHL (34).

Behavioral hearing tests in patients with NIHL can demonstrate deficits in speech recognition, in frequency and time resolution, and in other complex auditory tests. However, none of these tests has shown performance deficits specific to NIHL, and none has proved more useful than pure-tone threshold shifts for the early detection of NIHL.

EVALUATION AND DIAGNOSIS

Epidemiology

Hazardous noise exposure is common in our society; occupational noise and nonoccupational noise have each been estimated to cause 5% to 10% of the adult hearing loss burden in the United States (37). Table 157.1 shows the distribution of exposures in 19 industries believed by OSHA to contain most of the noisy workplaces in the United States (38): At that time, at least 5.1 million American industrial workers were exposed at levels exceeding 85 dBA, averaged over a workday (massive job losses in American manufacturing in the past two decades have almost certainly reduced those numbers). Sadly, no more recent data are available since that 1981 survey. Hazardous nonoccupational exposure is much more prevalent; the National Rifle Association estimates that 65 million Americans own guns (www.nraila.org, 2004), and many of them participate in hunting or target shooting. Significantly, firearms and occupational noise exposure often go together. The prevalence of handicapping NIHL in men has been estimated at 1.7% (39).

TABLE 157.1 NOISE EXPOSURE IN 19 US INDUSTRIES (1981)[a]

Level (dBA)	Workers	Total (%)
<80	6,987,000	46.88
80–85	2,793,000	18.74
85–90	2,244,500	15.06
90–95	1,636,500	10.98
95–100	815,200	5.47
>100	427,700	2.87

[a]Machinery, transportation equipment, electrical machinery, fabricated metals, food, apparel, primary metals, textiles, printing and publishing, utilities, lumber and wood, rubber and plastics, stone and glass, chemicals, paper, furniture and textiles, petroleum and coal, tobacco, and leather.

Damage Risk Criteria

Animal research has been essential in describing the pathogenesis of NIHL and some of its features; however, the risk of human hearing loss with various exposures can be estimated only from epidemiologic studies. The results of many such studies measuring the hearing of noise-exposed workers have been generally consistent; good summaries and professional consensus statements can be found in publications by ANSI (22) and OSHA (38).

Levels below about 80 dBA pose negligible risk to human hearing over a working lifetime. Above 85 dBA, risk grows rapidly for the high frequencies and more slowly for lower frequencies. Figure 157.5 shows the growth of NIPTS as a function of duration of employment for two frequencies (1 and 4 kHz) and two exposure levels (85 and 100 dBA) according to OSHA (38). Median threshold shifts are shown; half of all workers would show more shift, and half would show less shift than indicated. No curve is plotted for 1 kHz at 85 dBA because less than 1 dB of shift is predicted even after 40 years. Note that at 4 kHz, NIPTS grows rapidly over the first 10 years and then reaches a plateau. For 1 kHz, growth is somewhat more gradual, but more than 50% of NIPTS is accrued in the first 10 years.

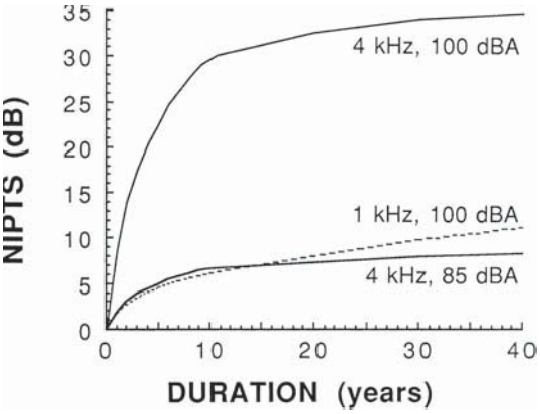

Figure 157.5 Median NIPTS as a function of exposure duration for 4 kHz (85 and 100 dBA) and 1 kHz (100 dBA).

Similar NIPTS curves are shown in Figure 157.6, using the pure-tone average (PTA) for 0.5, 1, 2, and 3 kHz (speech frequency average used in the American Medical Association [AMA] method of estimating "binaural hearing impairment" [BHI]). It is interesting to compare these curves with age-related permanent threshold shift (ARPTS) curves for men and women (Fig. 157.7), again for the 0.5, 1, 2, and 3 kHz PTA (23,24). ARPTS is an accelerating process (i.e., the rate of change of hearing loss increases with time), whereas NIPTS is a decelerating process (i.e., the rate of change decreases with time). This contrast can be helpful in determining the relative contribution of these two sources of hearing loss in individual cases.

Data like these can be used to estimate the median hearing loss for a population of workers with a given gender, age, duration, and level of exposure. The median expected hearing loss (0.5, 1, 2, and 3 kHz PTA) for 65-year-old men with 40 years of exposure at 90 dBA would be about 21 dB HL (15 dB aging plus 6 dB NIPTS), using the data from Figures 157.6 and 157.7. A greater loss than this prediction could be due to specific otologic disease, to above-average susceptibility to aging and/or noise, to undocumented noise exposure, or to a combination of factors.

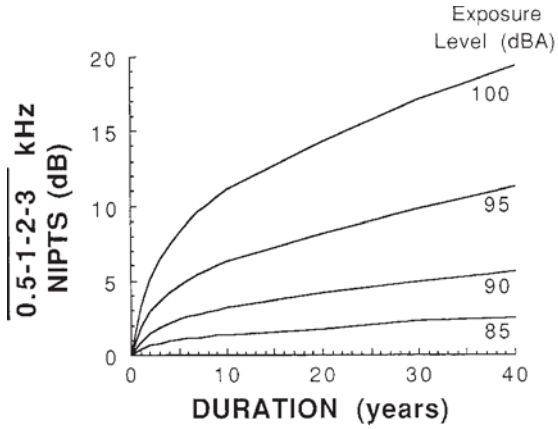

Figure 157.6 Median NIPTS for the PTA (0.5, 1, 2, and 3 kHz) as a function of exposure duration, for different exposure levels (85 to 100 dBA).

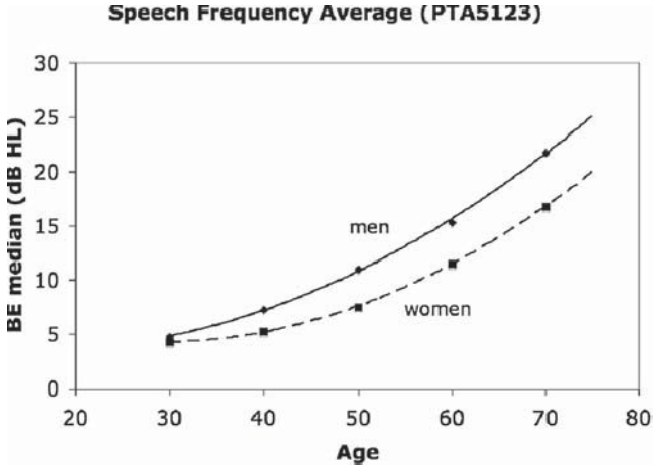

Figure 157.7 Median better-ear PTA hearing thresholds (0.5, 1, 2, and 3 kHz) for American men (*diamonds*) and women (*squares*) of different age groups (Hoffman HJ, Dobie RA, Ko Chia-Wen, et al. Hearing threshold levels at age 70 (65–74 years) in the unscreened older adult population of the United States, 1959–1962 and 1999–2006. *Ear Hear* 2012;33(3):437–440; Hoffman HJ, Dobie RA, Ko C-W, et al. Hearing threshold levels at age 70 (65–74 years) in the unscreened older adult population of the United States, 1959–1962 and 1999–2006. *Ear Hear* 2012;33(3):437–440). The smooth curves (*solid* for men, *dashed* for women) are quadratic fits to the plotted data points.

Nonoccupational Exposures

The most important nonoccupational cause of NIHL is gunfire. Impulse levels from rifles and shotguns can reach 170 dB at the shooter's ear. The left ear of a right-handed shooter is at greater risk because the right ear is somewhat protected by the head shadow. Data from the interindustry noise study showed that men in non-noisy jobs who reported hunting and shooting sustained hearing loss that was the equivalent of 20 years' occupational exposure at 89 dBA (40). Automobile airbags also produce very high impulse noise levels; they save lives but may cause acoustic trauma (41).

Exposures to leaf blowers, chain saws, and rock concerts can exceed 110 dBA. Very few people spend enough time in these exposures to cause NIPTS. The main exception is occupational exposure; thus, professional gardeners, forestry workers, and rock musicians are at considerable risk. Nonetheless, it is not unreasonable to wear hearing protection even for occasional exposures at such levels. Personal stereo systems (PSSs), including MP3 players, are capable of producing dangerous noise levels, but most users choose levels well below 90 dBA and durations below 20 hours per week. The most important risk of these devices is their use in a noisy work environment, where they can add to already-hazardous exposures.

There has been considerable media speculation about an "epidemic of hearing loss" attributable to PSSs, but scientific evidence of a link is lacking. One recent paper (42) found that teenagers in 2005 to 2006 had higher rates of hearing loss (mostly "slight," i.e., 15 to 25 dB HL) than in 1988 to 1994 and hinted that PSSs might be to

blame. If PSSs had caused an increase in hearing loss, one would expect to see several additional features: an increase in audiometric notches; an increase in bilateral high-frequency, rather than unilateral and/or low-frequency losses; and perhaps most importantly, a correlation between hearing loss (especially high-frequency loss) and reported noise exposure. None of these were seen in the cited paper. Another paper comparing the same two population surveys, using different methods (43), found no overall increase in hearing loss or in noise notches in the 2005 to 2006 data, but found that while the prevalence of noise notches had decreased in boys, it had increased in girls. Once again, there was no correlation between self-reported noise exposure, including the use of PSSs, and the risk of hearing loss. While extreme use of PSSs can cause hearing loss, it appears that this does not occur frequently enough to show up in population surveys.

Diagnosis of Noise-Induced Hearing Loss

In making a diagnosis of NIHL, the otolaryngologist should consider history, physical examination, audiometric findings (ideally over a period of many years), and sometimes the results of other tests. A history of occupational or nonoccupational noise exposure of hazardous intensity and duration should be sought. Noise exposure measurements from the workplace, if available, are most helpful. The history should document carefully all employment, including military service, which often includes noise exposure. Other etiologies of sensorineural hearing loss (heredity, ototoxicity, head injury, etc.) are primarily excluded by history. Physical examination excludes external ear and middle-ear disorders and occasionally may detect cranial nerve or balance abnormalities that suggest an acoustic tumor.

The pure-tone audiogram in early cases usually shows a notch at 3, 4, or 6 kHz (not pathognomonic for NIHL); this notch is often lost over the years as loss becomes more severe and as aging changes are added to NIPTS. PTA asymmetries greater than about 15 dB suggest either another etiology or asymmetric exposures (44). Rifles and shotguns are the most common source for asymmetric NIHL. Most indoor factory environments are highly reverberant so that one ear rarely receives significantly more noise than the other. It is important to document whether hearing protectors have been used, what types were used, and when that use began.

A series of audiograms prior to employment and at intervals throughout a worker's career is most helpful. As suggested earlier, hearing loss that accelerates in middle age without any increase in noise exposure probably is due primarily to aging rather than to noise.

Laboratory and imaging tests are of no value in establishing the diagnosis of NIHL but occasionally are indicated to rule out other disorders, especially acoustic tumor, when substantial asymmetries of hearing or other findings inconsistent with NIHL are present. The American College of Occupational and Environmental Medicine (2003) has recently updated its policy statement on the diagnosis of NIHL (excerpted in Table 157.2).

TABLE 157.2 PRINCIPAL CHARACTERISTICS OF OCCUPATIONAL NOISE-INDUCED HEARING LOSS[a]

- It is always sensorineural, affecting the hair cells in the inner ear.
- Because most noise exposures are symmetric, the hearing loss is typically bilateral.
- Typically, the first sign of hearing loss due to noise exposure is a "notching" of the audiogram at 3,000, 4,000, or 6,000 Hz, with recovery at 8,000 Hz. This notching is in contrast to age-related loss, which also produces high-frequency hearing loss, but in a down-sloping pattern without recovery at 8,000 Hz.
- Noise exposure alone usually does not produce a loss >75 dB in high frequencies, and 40 dB in lower frequencies. However, individuals with superimposed age-related losses may have HTLs in excess of these values.
- The rate of hearing loss due to chronic noise exposure is greatest during the first 10–15 y of exposure and decreases as the hearing threshold increases. This is in contrast to age-related hearing loss, which accelerates over time.
- Most scientific evidence indicates that previously noise-exposed ears are not more sensitive to future noise exposure and that hearing loss due to noise does not progress (in excess of what would be expected from the addition of age-related threshold shifts) once the exposure to noise is discontinued.
- In obtaining a history of noise exposure, the clinician should keep in mind that the risk of NIHL is considered to rise significantly with chronic exposures above 85 dBA for an 8-h TWA. In general, continuous noise exposure over the years is more damaging than interrupted exposure that permits the ear to have a rest period.

[a]Occupational NIHL, as opposed to occupational acoustic trauma, is hearing loss that develops slowly over a long period (several years) as the result of exposure to continuous or intermittent loud noise. Occupational acoustic trauma is a sudden change in hearing as a result of a single exposure to a sudden burst of sound, such as an explosive blast. The diagnosis of NIHL is made clinically by a medical professional and should include a study of the noise exposure history.

Compensation

Otolaryngologists are frequently asked to evaluate workers for state workers compensation programs and for federal agencies such as the Veterans Administration and the Department of Labor. Compensation for NIHL varies widely, as do the formulas used for assessing hearing handicap (45).

Hearing handicap has been defined as a disadvantage "sufficient to affect the individual's efficiency in the activities of daily living," specifically, interference with speech communication (46). Whereas most of the acoustic power in speech is concentrated below 1,000 Hz, most of the information content is in the higher frequencies. The typical patient with a handicapping degree of NIHL or age-related hearing loss can hear speech without difficulty because of the low-frequency power in vowel sounds but has difficulty discriminating among consonants because they are relatively high-frequency, low-intensity sounds. For example, *top* and *cop* may sound alike. These problems ultimately can lead to social withdrawal and isolation, depression, and a general reduction of quality of life. Depression also may be seen with tinnitus, which commonly accompanies NIHL.

In 1979, the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) revised their recommended method for evaluation of hearing handicap, which was subsequently accepted by the AMA (the AMA now uses the term "binaural hearing impairment" instead of "hearing handicap"). Most states have either adopted this method explicitly or have left the determination of hearing handicap to professional judgment. The AAO-HNS/AMA 1979 method (47) is based on several assumptions and has been validated against self-report of hearing difficulties in a recent large study (48):

1. Hearing loss does not begin to be handicapping until the PTA at 0.5, 1, 2, and 3 kHz exceeds 25 dB HL.
2. Handicap (as estimated by BHI) grows at the rate of 1.5% per decibel of hearing loss beyond 25 dB.
3. Because unilateral deafness is only a mild handicap, the two ears should not be equally weighted. Specifically, a 5 to 1 weighting favoring the better ear is used.

The monaural impairment (MI) for each ear is first calculated from the four-frequency PTA:

$$MI = 1.5\ (PTA–25)\ [\textit{Note: if PTA} < 25, \textit{MHI} = 0\%]$$

BHI, ranging from 0% to 100%, is then calculated as a weighted average favoring the better ear:

$$BHI = [5(MI_b) + (MI_w)]/6$$

where MI_b and MI_w represent the MI scores of the better and worse ears.

For example, consider a person whose thresholds are as follows:

Frequency (kHz)	Right Ear (dB)	Left Ear (dB)
0.5	15	20
1	25	40
2	35	60
3	45	80

The right (better) ear PTA is (15 + 25 + 35 + 45)/4 = 30 dB. The better ear MI score is (30 – 25) (1.5) = 7.5%.

The left (worse) ear PTA is (20 + 40 + 60 + 80)/4=50 dB. The worse ear MI score is (50 – 25) (1.5) = 37.5%.

BHI is [5(7.5) + (37.5)]/6 =12.5%.

Even when no other specific otologic disease is present, elevated thresholds in noise-exposed workers can usually be thought of as containing both age-related and noise-induced components. Age correction of audiograms is not appropriate for compensation assessment purposes. It is possible, however, to make reasonable estimates of the relative contributions of noise and aging, or of separate periods of noise exposure, in individual cases (20,49).

The physician's report of a compensation examination should be complete and concise and, most importantly, should offer clear diagnostic conclusions based on clinical and scientific evidence with some explanation of the reasons for those conclusions. If a particular diagnosis is "more probable than not" (probability > 50%), it can and should be stated as a "reasonable medical certainty"; this standard, which is typical for civil and workers' compensation cases, differs substantially from the "beyond a reasonable doubt" standard used in criminal trials. The AAO-HNS (49) has published guidelines for physicians' reports in such settings.

MANAGEMENT

Hearing Conservation

Since 1970, federal law has required most employers to prevent exposures exceeding 90 dBA averaged over an 8-hour day. The detailed requirements for occupational HCPs, however, were not published until much later (50).

Many noise exposures are not steady state; the noise may fluctuate in intensity throughout the day. Other occupational exposures may be brief, as when a worker spends less than 1 hour a day in a particularly noisy part of the factory. Considerable controversy exists about how to handle such exposure variations, largely because there are only scanty epidemiologic data relating NIPTS to brief and varying exposures. If exposures containing equal sound energy were equally hazardous, one would adopt a trading rule in which the permissible exposure time would be cut in half for each 3-dB increase in exposure level (sound power, i.e., energy per unit time, doubles for each 3-dB increment). However, there is frequently a degree of intermittency in

TABLE 157.3 PERMISSIBLE NOISE EXPOSURES

Duration Per Day (h)	Sound Level (dBA)
8	90
6	92
4	95
3	97
2	100
1.5	102
1	105
0.5	110
0.25	115

occupational noise exposures, thus reducing risk. For this reason, expert consensus led OSHA to adopt a 5-dB trading rule: A 4-hour exposure at 95 dBA and a 2-hour exposure at 100 dBA are considered equally as hazardous as an 8-hour exposure at 90 dBA. Each of these exposures would be considered to be 90 dBA "time-weighted average" (exposure level that if constant for 8 hours would be expected to pose the same risk of hearing loss as the briefer exposure in question). Time-intensity trading ends at 115 dBA: Above this level, OSHA permits only exposures of less than 1 second. This relationship between sound level and duration is shown in Table 157.3.

The maximum permissible exposure (without hearing protection) under OSHA regulations is 90 dBA TWA, but HCPs must be implemented for all workers whose exposures exceed 85 dBA TWA. Impulse noise exposure is limited to a 140-dB peak level.

The essential elements of an HCP are as follows:

- Noise exposure measurements
- Engineering or administrative controls to reduce exposure
- Periodic audiometry with follow-up and referral
- Use of personal hearing protection devices (HPDs)
- Education, motivation, and counseling
- These elements should be supported by an administrative component that includes supervision, record keeping, and program evaluation.

Measurements of noise exposure may be performed with sound level meters or devices called noise dosimeters, which attach to a worker's clothing and automatically compute his or her TWA exposure. Exposures that exceed permissible limits can be reduced by noise control or by reducing the time that employees spend in the noise. In situations in which neither engineering nor administrative controls can reduce exposures below 85 dBA TWA, a program of annual audiometry must be instituted. Although workplace audiometry is less reliable than clinical testing, PTA changes of 10 dB or more usually indicate real hearing changes (51). OSHA defines a standard threshold shift (STS) as a 10-dB or greater increase in threshold for the 2-, 3-, and 4-kHz average in either ear. Unfortunately, OSHA does not mandate otologic referral, even for large or asymmetric losses, although disorders other than NIHL are often found in such cases (52). Workers who demonstrate STS or who have exposures above 90 dBA TWA must use HPDs (earplugs, earmuffs).

Although the "noise reduction ratings" on the package labels of HPDs are typically 20 to 30 dB or even higher, these numbers reflect ideal fitting in laboratory conditions. Real-world attenuation values are much lower: On the average, premolded earplugs offer about 10-dB attenuation of A-weighted levels, formable foam plugs about 15 dB, and earmuffs about 20 dB. If worn only 4 hours out of a steady 8-hour noise exposure, no HPD can provide more than 5 dB of effective attenuation. Recently, there has been great interest in electronic noise cancellation headsets, which attempt to deliver a sound wave to the ear that is exactly out of phase with the ambient noise. These devices can effectively cancel out only low-frequency noises (up to about 500 Hz), and they can thus be quite helpful in environments where the noise is predominantly low frequency, such as in private aviation. Unfortunately, the most hazardous spectral components for most occupational and recreational noises are well above 500 Hz; thus, noise cancellation has been of very little value in HCPs. In contrast, another type of electronic HPD has proved to be very useful in situations where the hazardous noise is only intermittent (such as recreational shooting): These "level-dependent" HPDs have an external microphone, an internal speaker, and circuitry that allows sounds below about 85 dB to pass into the ear while louder sounds are blocked.

The differences in protection afforded by various HPDs, when worn properly, are small compared with variations in protection that occur with improper or negligent use. Therefore, the most important factors in choosing an HPD are proper fit and acceptance by the worker. Counseling and motivation are important. Many workers fear they will miss important communications or warning signals with HPDs in place. In fact, detection of such signals is usually not impaired. Speech and other signals need to be at a high level to be heard over industrial noise anyway, and with the HPD in place, both signal and noise are equally reduced. Some workers with high-frequency hearing loss perform more poorly than normal-hearing persons in detecting and discriminating signals in noise with HPDs in place (53); this problem can often be ameliorated by using HPDs with less high-frequency attenuation, which may provide adequate protection without making high-frequency signals inaudible.

Clinical Management

Many physicians have advocated treatments, usually based on vasodilatation or hemorheologic effects, for acute acoustic trauma. Considerable recovery of hearing is part

of the natural history of such events, however, and no well-controlled studies have yet demonstrated benefit for any treatment, except in animals (not human patients) given antioxidants (e.g., vitamins A, C, and E; N-acetyl L-cysteine), vasodilators (e.g., magnesium), or other drugs (e.g., furosemide) prior to or during excessive noise exposure. This continues to be an active area of research, and future studies may yet show that drugs, vitamins, and/or nutritional supplements have a role in the treatment and prevention of NIHL (54–56).

Counseling to prevent further hearing loss is crucial. Exposed workers who are not enrolled in occupational HCPs need to be scheduled for periodic monitoring audiometry and should be counseled regarding the appropriate use of HPDs. Hearing aids are helpful when hearing loss becomes handicapping, but of course they do not restore normal hearing.

Counseling hearing-impaired workers or their employers regarding fitness for continued safe and productive employment is extremely difficult. Factors to consider include not only the degree of hearing loss but also the acoustic environment at work, the communicative demands of the job, and nonauditory attributes of the worker, such as age, experience, linguistic background, and cognitive status (57).

NONAUDITORY EFFECTS

Loud noise interferes severely with speech communication at about the same levels at which hazard to hearing begins. This information can be useful in counseling and in assessing compensation claims. If a worker states that the workplace is noisy enough that he or she must speak very loudly or shout to converse at ordinary conversational distances, then, even in the absence of sound level measurements, it can be concluded that levels are probably over 80 dBA.

Other nonauditory effects of noise, including annoyance, sleep disturbance, and physiologic changes (in blood pressure, catecholamine secretion, and so on), are controversial. Certainly, annoyance and sleep disturbance may occur at levels far below any hazard for NIHL (58,59). An unwanted noise, such as a dripping faucet or a neighbor's party, even if quite faint, can be annoying and stressful. These effects are not due to the physical properties of the noise (intensity, spectrum, time) but to cognitive and psychological factors (60). It is impossible to predict these types of effects with a sound level meter. It is probably safe to say that most experts believe that no adverse long-term health effects of noise exposure have been demonstrated at exposures below those that could cause NIHL.

THE IMPORTANCE OF PREVENTION

NIHL is by far the most important preventable cause of hearing loss in adults. Noise reduction and use of HPDs, in occupational HCPs mandated since 1983, have already prevented many workers from suffering hearing impairment. Nevertheless, NIHL continues to be an important public health problem. Major coverage gaps include small employers, industries that are not currently subject to detailed OSHA regulations (construction, agriculture, oil and gas drilling), and nonoccupational noise exposure (especially shooting). Otolaryngologists can help by asking their patients about noise exposure and by providing hearing protection, counseling, and periodic audiometry for exposed patients who are not well covered at work. We should also educate our colleagues in primary care about the roles they can play in prevention of NIHL. Some have advocated more stringent hearing conservation regulations, such as lowering the permissible exposure level or the way it is calculated. But in the author's opinion, adequate enforcement of current OSHA regulations, implementation of HCPs for currently uncovered entities, and effective physician involvement would save far more hearing than any change in current OSHA regulations.

ACKNOWLEDGMENTS

Drs. Dixon Ward, William Melnick, Donald Henderson, and Jack Mills read earlier versions of the manuscript and made helpful suggestions. Michael Wilson prepared the figures; Julie Estrada and Mary Brown typed the original manuscript.

HIGHLIGHTS

- NIHL, although not medically or surgically treatable, is the major preventable cause of hearing loss in the United States.
- NIPTS grows rapidly in the high frequencies (3 to 6 kHz) and then decelerates after about 10 years.
- After about 10 years at constant exposure levels, threshold shifts at lower frequencies (especially 2 kHz) begin to predominate.
- Within the organ of Corti, the outer hair cells are most susceptible to noise-induced damage.
- Workplace exposures below 80 dBA pose negligible risk to human hearing; exposures at levels above 85 dBA may cause significant noise-induced threshold shift.
- In contrast to noise-induced loss, age-related hearing loss is an accelerating process (rate of change increases with time).
- The most important nonoccupational cause of NIHL is gunfire.
- Federal regulations forbid occupational exposures over 90 dBA TWA (8-hour equivalent) without hearing protection but require HCPs for all workers whose exposures exceed 85 dBA TWA.

- The need to shout to converse in the workplace or a worker's complaint of temporary fullness, tinnitus, or muffled hearing after work usually indicates the presence of potentially hazardous noise levels.
- Diagnosis of NIHL should not be made on the basis of audiometric contour alone, but must include a careful history of occupational and nonoccupational noise exposure.

158 Ototoxicity

Kay W. Chang

It is important for physicians to be aware of the large number of systemic and topical agents that can cause functional impairment and cellular damage to the inner ear. Ototoxicity-induced hearing loss can result in significant disability to the affected individual, especially young children who are still in the process of speech and language development. Ototoxic effects on the vestibular system can result in significant balance disorder and impair even simple activities of daily life. Recognizing the early signs of ototoxicity may allow for discontinuation or reduction of the offending agent, thus minimizing permanent hearing and balance impairment. As our knowledge of the genetics of ototoxicity improves, it may be possible to identify patients who are at high risk of developing ototoxicity prior to exposure to the drug. Furthermore, a number of promising otoprotective agents are emerging that may also diminish or completely prevent ototoxicity.

SYSTEMIC OTOTOXICITY

Table 158.1 summarizes the major agents implicated in ototoxicity. The categories that are responsible for the majority of ototoxicity clinically observed in present-day medicine are the aminoglycosides and platinum-containing chemotherapy agents.

Aminoglycosides

Aminoglycoside antibiotics have been an important part of our antibacterial drug armamentarium since the discovery of streptomycin in 1943 by Waksman, who was awarded the Nobel Prize for this discovery. While they possess potent activity against *Pseudomonas aeruginosa* and most other aerobic gram-negative bacilli, their toxicity has resulted in restrained use in developed countries with the introduction of broad-spectrum cephalosporins, carbapenems, and fluoroquinolones. However, since many aminoglycosides are significantly cheaper than alternative drugs, aminoglycoside use remains relatively high in emerging countries in East Asia and Latin America. Aminoglycosides are also frequently utilized in patients with cystic fibrosis. In the United States, eight aminoglycosides (gentamicin, tobramycin, amikacin, streptomycin, neomycin, kanamycin, paromomycin, and spectinomycin) are approved by the FDA (1). Aminoglycosides ending in "mycin" are fermentation products or semisynthetic derivatives from *Streptomyces*, while those ending in "micin" are products of *Micromonospora* (2). Nephrotoxicity occurs in 5% to 25% of patients receiving aminoglycosides (2–7), while ototoxicity results in hearing loss in 3% to 13% (8–13), and vestibular impairment in 1% to 11% (4,9,14–17).

It is somewhat uncommon to have both vestibular and cochlear symptoms in the same patient; however, either or both may occur with any of the aminoglycosides (17). Auditory symptoms of hearing loss and tinnitus are most prevalent with neomycin, followed in order of decreasing toxicity by gentamicin, tobramycin, amikacin, and netilmicin (2,9,16,18,19). Vestibular symptoms of dizziness, imbalance, nausea, and oscillopsia are seen most with gentamicin and tobramycin, less frequent with amikacin, and least frequent with netilmicin (14,16,17). Aminoglycosides have been found to be the most common cause of bilateral vestibular dysfunction (20).

Platinum Compounds

In 1965, Barnett Rosenberg discovered that electrolysis of platinum electrodes generated a soluble platinum complex that inhibited binary fission in *Escherichia coli* (21). Cisplatin was noted to be the most active platinum complex in experimental tumor systems, and since the mid-1970s has been one of most widely used chemotherapy agents. Platinum compounds are non-cell-cycle-specific agents that inhibit deoxyribonucleic acid (DNA)

TABLE 158.1 OTOTOXIC AGENTS

- **Aminoglycosides**
  - Gentamicin
  - Tobramycin
  - Neomycin
  - Amikacin
  - Streptomycin
  - Kanamycin
  - Paromomycin
  - Spectinomycin
  - Netilmicin
  - Dihydrostreptomycin
- **Cytotoxic agents**
  - Platinum compounds
    - Cisplatin
    - Carboplatin
    - Oxaliplatin
    - Others (nedaplatin, AMD-473, satraplatin)
  - Vinca alkaloids
    - Vincristine
    - Vinblastine
    - Vinorelbine
  - Bleomycin
  - Nitrogen mustard
- **Loop diuretics**
  - Furosemide
  - Ethacrynic acid
  - Bumetanide
  - Others (piretanide, azosemide, triflocin, indapamide)
- **Macrolides**
  - Erythromycin
  - Azithromycin
  - Clarithromycin
  - Ketolides (Telithromycin)
- **Vancomycin**
  - (primarily in conjunction with aminoglycosides)
- **Iron-chelating agents**
  - DFO
- **Anti-inflammatory agents**
  - Salicylates—ASA
  - NSAIDs
  - Quinine
- **Heavy metals**
  - Mercury
  - Lead
- **Arsenic**
- **Antiseptic/disinfectant agents**
  - Chlorhexidine
  - Alcohol
- **Chloramphenicol**
- **Polymyxin**

replication, inducing apoptosis and/or necrosis in tumor cells. The mechanism of cisplatin ototoxicity is multifactorial with changes noted in the stria vascularis, spiral ganglion cells, and outer hair cells (OHCs) (22). In contrast, carboplatin appears to be preferentially toxic to the inner hair cells (IHCs) (23–25).

Cisplatin is associated with severe nausea and vomiting in almost all patients (26). 5-hydroxytryptamine receptor antagonists can dramatically reduce the severity of nausea and vomiting and allows cisplatin to be administered in an ambulatory care setting (27). Nephrotoxicity of cisplatin can be severe but can also be moderated with aggressive hydration with normal saline, together with infusion of hypertonic saline and mannitol-induced diuresis (28–30). Amifostine has also been shown to protect against cisplatin-induced nephrotoxicity (31) though it has not been able to protect against ototoxicity (32,33). Neurotoxicity of cisplatin includes peripheral sensory neuropathy, autonomic neuropathy (most commonly producing constipation), and ototoxicity (high-frequency hearing loss). Neuropathy can occur in 30% to 50% receiving high cumulative doses of cisplatin (34,35). Ototoxicity can occur at much lower doses, and has become the major dose-limiting toxicity of this drug, particularly in young children (36).

The reported incidence of cisplatin ototoxicity varies from 9% to 91%, due to differences in chemotherapy regimens, patient populations, the definition of ototoxicity, and variations and inconsistencies in the assessment and grading of the hearing loss (37–48). The clinical presentation of cisplatin ototoxicity includes tinnitus and a bilateral and usually symmetric high-frequency sensorineural hearing loss (SNHL) with a progression toward lower frequencies with cumulative doses. The hearing loss is permanent and usually irreversible, though occasionally recovery can be observed (49–52), as well as worsening of hearing loss following cessation of treatment (53–56). Predisposing risk factors include age extremes (particularly young children), previous or concurrent cranial irradiation, renal disease or insufficiency, IV bolus administration or high cumulative dosage of cisplatin, coadministration with aminoglycosides or loop diuretics, excessive noise exposure, poor volume status, previous history of hearing loss, and concomitant use of other ototoxic chemotherapy agents (cytarabine, bleomycin, nitrogen mustard, vincristine, and vinorelbine) (57–65).

The rate of ototoxicity when carboplatin is given alone with conventional dose regimens is generally reported in only 1% of patients. However, the incidence following high-dose or combination therapy with cisplatin rises to 33% to 82% (66–70). Nedaplatin is a second-generation platinum compound that may be less ototoxic than cisplatin, but more ototoxic than carboplatin (71–73). Oxaliplatin is a third-generation cisplatin analogue that is not associated with either nephrotoxicity or ototoxicity (74–77). However, peripheral sensory neuropathy aggravated by exposure to cold is a significant dose-limiting toxicity (78).

Vinca Alkaloids

Vinca alkaloids are antitumor drugs derived from an alkaloid obtained from the periwinkle plant *Vinca rosea* (vincristine, vinblastine) or a semisynthetic alkaloid (venorelbine)

(79). Sporadic reports suggest that vinca alkaloids are associated with risk for ototoxicity at higher doses; however, it is impossible to isolate vinca alkaloids as the responsible agent since they are typically used with other ototoxic chemotherapeutic agents (e.g., cisplatin) (57,61,80–82). A rare otolaryngologic complication of vincristine is vocal cord paralysis (83).

Loop Diuretics

Furosemide, bumetanide, and ethacrynic acid are the most commonly used loop diuretics, with ethacrynic acid reserved for those cases allergic or refractory to furosemide (84). Loop diuretics are used in the treatment of congestive heart failure, renal failure, cirrhosis, and hypertension. They are widely used in the neonatal intensive care unit in the treatment of bronchopulmonary dysplasia (85). Risk factors for ototoxicity include renal impairment, prematurity, and associated aminoglycoside use (86). The mechanism of ototoxicity appears to be a dose-related, reversible reduction in endocochlear potential (87,88).

The ototoxicity of ethacrynic acid initially was reported to be temporary (89–92); however, other reports documented permanent hearing loss in patients with impaired renal function (93–99). The incidence of ototoxicity from ethacrynic acid was estimated to be 7 patients per 1,000 treated (100). Rapid infusion (101,102) and large bolus dosings (103) of furosemide have been noted to cause a high incidence of hearing loss. While permanent hearing loss with furosemide after IV administration has been reported (104), most cases of furosemide ototoxicity have been reversible (105,106). Bumetanide is more potent but less ototoxic than furosemide (107–109); however, its higher cost appears to be a rate-limiting factor in its clinical use.

Macrolides

Erythromycin works by inhibiting protein synthesis in bacteria by reversibly binding 50S ribosomal subunits (110). Most reported ototoxicity has been reversible (111–118), though some irreversible cases have also been reported (119,120). Renal impairment (117,121–124), hepatic impairment (125), and transplant recipients (126,127) appear to have increased risk for ototoxicity. The second-generation macrolide azithromycin has been reported to cause reversible hearing loss in HIV patients (128–130) and elderly patients (131,132). There is a single case report of complete deafness (133) as well as a few of irreversible hearing loss (134,135). Clarithromycin likewise has been reported to sometimes result in ototoxicity (136–138). Telithromycin is a ketolide and represents a newer class of macrolide antibiotic with zero cases of ototoxicity reported among 2,045 patients in eight phase III trials (139).

Vancomycin

Vancomycin has been primarily associated with ototoxicity when given in conjunction with an aminoglycoside (140,141). However, in a group of patients not receiving any other ototoxic agents, 1/31 (3.2%) receiving once-daily vancomycin dosing and 5/32 (15.6%) receiving twice-daily vancomycin dosing developed hearing loss (142). Age extremes may be another risk factor. Ototoxicity after an average of 27 days of vancomycin therapy was also found in 19% of patients older than 53 years old (143). A recent study also suggested an increased risk of vancomycin ototoxicity in neonates (144).

Salicylates, Nsaids, and Quinine

Acetylsalicylic acid (ASA), commonly known as aspirin, is one of the most widely used drugs. ASA ototoxicity has been reported to occur in 11 per 1,000 patients (100,145), and results in tinnitus and a reversible mild to moderate bilaterally symmetric hearing loss (146). Recovery usually occurs 24 to 72 hours after cessation of the drug (147). Onset of tinnitus has been often used as the earliest clinical sign of salicylate toxicity (148–150). Nonsteroidal anti-inflammatory drugs (NSAIDs) share similar therapeutic actions and ototoxicity side effects with salicylates (147,151–153).

Quinine is an antimalarial drug that has been decreasing in use due to less toxic semisynthetic derivatives; however, it is still occasionally used for nocturnal leg cramps (147). Large doses of quinine produce reversible hearing loss and tinnitus, similar to salicylates (86,147,154,155). Transient vestibular effects have also been noted with quinine (156).

Iron-Chelating Agents

Deferoxamine (DFO) is an iron-chelating agent used in the treatment of acute iron intoxication and chronic iron overload secondary to multiple transfusions (157). Ototoxicity from DFO was first recognized in thalassemia major patients in the 1980s (158–162). Since then, a wide range in incidence of SNHL (12% to 56%) has been published (163–168).

Heavy Metals

Toxic levels of mercury have been reported to result in hearing loss (169–173). Lead toxicity has multisystemic toxic effects, particularly involving the peripheral and central nervous systems (174). Hearing loss has been demonstrated in both children (175,176) and lead-exposed workers (177). Experimental studies suggest that lead toxicity affects neural transmission in auditory pathways (178,179).

TOPICAL OTOTOXICITY

Ototopical Ear Drops

Animal data have demonstrated that nearly all aminoglycosides used in the middle ear as topical otic preparations are ototoxic (180). There have been long-running discussion and debate whether topically applied aminoglycosides cause similar injury in the human inner ear (181–185). The round window membrane is a potential access point between the middle ear and the inner ear, but in humans is positioned in a more protected location than in animal models and also much thicker (186–189). Furthermore, in the setting of middle ear inflammation when topical drops are likely to be applied, the round window becomes less permeable (189,190). Nonetheless, use of otic drops for extended duration in humans has been reported to result in ototoxicity (186,191,192). Furthermore, gentamicin can be topically applied to intentionally ablate vestibular function (193). A consensus AAO-HNS panel in 2004 found 54 cases of gentamicin vestibular toxicity of which 24 also had hearing loss, and 11 cases of neomycin/polymyxin auditory toxicity of which 2 had vestibular symptoms (194), and made the following recommendations (195):

1. When possible, topical antibiotic preparations free of potential ototoxicity should be used in preference to ototopical preparations that have the potential for otologic injury if the middle ear or mastoid is open.
2. If used, potentially ototoxic antibiotic preparation should be used only in infected ears. Use should be discontinued shortly after the infection has resolved.
3. If potentially ototoxic antibiotic drops are prescribed for use in the open middle ear or mastoid, the patient/parent should be warned of the risk of ototoxicity.
4. If potentially ototoxic antibiotics are prescribed, the patient should be specifically instructed to call the physician or return to his or her office if the patient develops dizziness, vertigo, hearing loss, or tinnitus.
5. If the tympanic membrane is known to be intact and the middle ear and mastoid are closed, then the use of potentially ototoxic preparations presents no risk of ototoxic injury.

The widespread availability of nonototoxic fluoroquinolone topical agents (ofloxacin, ciprofloxacin) coupled with these consensus recommendations, has resulted in a significant decrease in the clinical use of aminoglycoside otic solutions.

Other Ototoxic Topicals

Chloramphenicol has a wide antibacterial spectrum; however, its use in modern days has been limited due to significant reported ototoxicity (196,197).

Chlorhexidine has been demonstrated to have significant ototoxicity in many animal models (198–202), though not definitively shown in humans. Likewise, ethyl alcohol has also been shown to produce ototoxicity in animals (202). Chlorhexidine and alcohol skin preparations have therefore been recommended to be avoided during ear surgery when a tympanic membrane perforation is present.

GENETICS OF OTOTOXICITY

Genetic Factors in Aminoglycoside Ototoxicity

The existence of families with multiple individuals with aminoglycoside ototoxicity has been noted since 1957 (203–207). Examination of inheritance patterns suggested a maternally transmitted mitochondrial defect as a possible etiology (203,207). The A1555G mutation in the mitochondrial 12S ribosomal ribonucleic acid (rRNA) gene was eventually implicated as the causative factor since this small rRNA had been shown to bind to aminoglycosides and to harbor resistance mutations in yeast and *Tetrahymena* (208–211). The A1555G mutation has since then been found in multiple families with aminoglycoside ototoxicity (212–219). C1494T is a different mutation in the 12S rRNA that was later identified in a large Chinese pedigree (220).

Due to their low cost and high availability, the use of aminoglycosides is widespread in China, and up to 22% of all deaf-mutes in one district could trace the cause to aminoglycoside use, 28% of them having other relatives with aminoglycoside ototoxicity (207). It is estimated that up to a third of patients with aminoglycoside ototoxicity in China have the A1555G mutation (221). In the United States, a study showed that 17% of patients with aminoglycoside ototoxicity demonstrated a mitochondrial susceptibility mutation (222).

As rapid screens for multiple mitochondrial susceptibility mutations (A1555G, C1494T, T1095C, 961delT+C(n), A827G) become more available (223), it may be possible to develop aminoglycoside treatment strategies that prevent irreversible cochlear damage, or identify patients for alternative antibiotic regimens (224). A recent screening study of 865 newborns in China identified six (0.7%) newborns with homoplasmic A1555G mutations that all passed newborn hearing screening (225). Likewise, a study of 8,974 Brazilian neonates found among 17 who failed transient-evoked otoacoustic emissions (TEOAEs), 3 individuals with A827G mutation (226).

Genetic Factors in Cisplatin Ototoxicity

An increasing number of pharmacogenomic studies investigating genetic factors in cisplatin ototoxicity have been performed. Because megalin is highly expressed in renal proximal tubular cells and marginal cells of the inner ear and also because it has been associated with the uptake

of aminoglycosides, megalin was investigated for a candidate gene approach, and an association between a single nucleotide polymorphism rs2075252 of the megalin gene was found more often in those with intact hearing after cisplatin therapy (227).

Functional polymorphisms in cisplatin detoxifying enzymes such as Glutathione-S-Transferase (GST) may play also a role in protection from cisplatin ototoxicity. The genes encoding the enzymes GSTM1, GSTT1, and GSTP1 are polymorphic in humans and non-functional variants are commonly found in Caucasians. A significant association between cisplatin induced hearing loss and expression of GSTM3 was found in 39 adults (228). In a larger cohort of 173 adult testicular cancer survivors, a *GSTP1* variant was associated with protection against hearing (229). This GST genotype has also been shown to be associated with less oxaliplatin-induced neuropathy (230).

The most promising study of the role of genetics in cisplatin toxicity involved two cohorts identified through the Canadian Pharmacogenomics Network for Drug Safety. Utilizing a gene chip comprised of variants in 220 drug metabolism genes, it was found that genetic variants of TPMT (thiopurine S-methyltransferase, odds ratio = 17) and COMT (catechol O-methyltransferase, odds ratio = 5.5) were significantly associated with cisplatin-induced hearing loss. Furthermore, the number of risk alleles carried by an individual was inversely related to time to deafness (i.e., those who carried at least three out of four risk alleles had a rapid decline in their hearing, often with their first dose of cisplatin). The combination of TPMT and COMT genotypes was able to identify cisplatin-induced deafness with a positive predictive value of 92.9% and a negative predictive value of 48.6% (231).

OTOPROTECTIVE STRATEGIES

Mechanisms of Ototoxicity

There are both similarities and significant differences in the mechanisms by which cisplatin and aminoglycosides cause hearing loss and vestibular dysfunction. All ototoxic drugs induce dose-dependent death of cochlear hair cells. OHCs are more susceptible than IHCs to death caused by exposure to either cisplatin or aminoglycosides (232,233). Cochlear hair cell death becomes first evident at the base and progresses apically with continued exposure to the drug (234). Both cisplatin-induced and aminoglycoside-induced hair cell death are significantly inhibited by broad-spectrum inhibition of caspases (235–240). Cisplatin also induces degeneration of the stria vascularis, decreasing the number of marginal and intermediate cells, as well as spiral ganglion cells (241,242).

Inner ear sensory cells reside within a blood–labyrinth barrier (BLB), similar to the blood–brain barrier (BBB). Compounds essential for cellular function are transported through the endothelial cells that form the BLB. Increase in permeability between adjacent endothelial cells in the BLB rapidly induces loss of the endolymphatic potential (EP) with consequent elevation of sensory thresholds. However, ototoxins, such as aminoglycosides and cisplatin, traverse the intact BLB by trafficking mechanisms that remain poorly understood.

Antioxidants as Otoprotective Agents

Understanding the mechanisms underlying cisplatin ototoxicity has led to recognition of the role antioxidants may play in protecting the inner ear from ototoxicity. Cisplatin may permeabilize mitochondria in cochlear hair cells to release proapoptotic factors, or generate toxic levels of reactive oxygen species (ROS), each of which can initiate cell death mechanisms (243–246). ROS formation has also been implicated as a major mediator of cisplatin-induced hair cell death (247–252). Increased pools of ROS not only damage proteins and lipids but also deplete the cell's intrinsic antioxidant molecules (253,254). Cisplatin is activated by the replacement of one of its two chloride groups by a water molecule. This activated "mono aqua" cisplatin reacts preferentially with antioxidant molecules, particularly glutathione and metallothioneins. In cancer cells with very high levels of glutathione, cisplatin can be effectively bound up by the glutathione, reducing cisplatin's chemotherapeutic efficacy in these tumors (255). Cisplatin-induced ototoxicity is reduced in animal models by a variety of antioxidants, including N-acetylcysteine (256–258), sodium thiosulfate (259–261), D-methionine (262,263), α-lipoic acid (264,265), tocopherol (266,267), salicylate (268), ebselen (265,269), and amifostine (259,270). Antioxidant protection of cisplatin-induced ototoxicity has not been as extensively tested in humans, though amifostine does not seem to be very effective (32,33,271,272) while sodium thiosulfate has shown promising results (273–276).

Transport Mechanisms

Ototoxic drugs are able to traverse the intact BLB, yet the trafficking mechanisms by which they cross the BLB remain poorly understood. A trans-strial trafficking route from strial capillaries to marginal cells, followed by clearance into endolymph has been proposed for aminoglycosides (277). Another possible route for traversing the BLB into perilymph and subsequently into endolymph may be via transcytosis across the epithelial perilymph/endolymph barrier. For cisplatin to cross either of these trafficking routes, the positive EP (EP, +85 mV) must be overcome prior to entry of cationic cisplatin into endolymph, presumably by active trafficking.

Ototoxic aminoglycosides enter hair cells via apical endocytosis or permeation through the stereociliary mechanoelectrical transduction channels *in vitro* (278,279).

The same has not been demonstrated for cisplatin. However, a number of active copper transport mechanisms for cellular uptake of cisplatin have been proposed. Transfection of human and yeast cells with the copper transporter-like 1 (CTR1) gene to induce protein expression of CTR1 increased cellular uptake of cisplatin by 50% (280–283). Cultured cell lines with greater resistance to cisplatin toxicity have significantly lower expression of CTR1 (284,285). The copper-transporting adenosine triphosphatases 7A and 7B (ATP7A and ATP7B, respectively) have also been linked to cytoplasmic cisplatin sequestration and export out of the cell (286). Increased expression of ATP7A or ATP7B results in increased resistance to cisplatin toxicity in tumor cell lines (284,287). Following cellular uptake, ATP7B binds to cisplatin and is transported into intracellular vesicles (288).

Another transporter, OCT2, has also been associated with cisplatin excretion in the kidneys (288–290), and OCT1/2 double knockout mice are protected from cisplatin-induced ototoxicity (291). Although CTR-1 and OCT2 are present in the stria vascularis (291,292), the cellular distribution of these transporters has yet to be reported in the inner ear. CTR1, ATP7A, ATP7B, and OCT2 are all highly expressed in the choroid plexus, part of the BBB that regulates ion and substrate trafficking into and out of cerebrospinal fluids (293–295).

Several platinum-based derivatives (oxaliplatin, carboplatin) have been developed to reduce their ototoxic and nephrotoxic side effects. The reduced ototoxicity is due to the replacement of chloride ions that are integral for DNA adduct formation, thus leading to reduced platinum–DNA adduct formation in inner ear tissues. OCT2 is reported to have greater specificity for oxaliplatin (296), and a greater understanding of how transport genes such as OCT2 and CTR1 modify the uptake and trafficking of ototoxic drugs into the cochlear hair cells may result in future chemical modifications to further reduce ototoxicity (297,298).

CLINICAL MONITORING OF OTOTOXICITY

Basic audiologic assessment with pure-tone thresholds from 250 to 8,000 Hz remains an important part of ototoxicity monitoring. The basic battery should include measurement of both air and bone conduction thresholds and tympanometry if any hearing loss is identified, in order to rule out an incidental conductive involvement. Ideally, a baseline assessment prior to ototoxic drug administration is necessary to definitively demonstrate the presence of ototoxicity (299). This is especially true in the elderly population, where there exists a high incidence of preexisting high-frequency hearing loss. The pediatric oncology population may provide significant challenges, especially children developmentally younger than 3 years of age. Many of these young children can be quite sick and uncooperative to ear-specific behavioral testing (37), and the incidence of middle ear dysfunction resulting in conductive overlays is also higher in this population.

Ototoxic drugs have been demonstrated to preferentially affect OHCs of the basal cochlear turn (8,300,301). High-frequency audiometry (HFA) of frequencies above 8,000 Hz has been shown to detect aminoglycoside-induced or cisplatin-induced ototoxic losses well before changes become evident on conventional audiometry (302–317). HFA has been shown to be efficacious in a quiet hospital room for bedside testing (318,319). High-frequency auditory brainstem response testing may also be utilized (320,321). However, HFA does require more frequent calibration and special earphones, and thus is not readily available at many institutions.

Distortion product otoacoustic emissions (DPOAEs) (322,323) or TEOAEs (324,325) are another modality for detecting ototoxicity. Otoacoustic emissions (OAEs) can be a particularly useful complement to behavioral measures in young children since they are objective and allow cross-check of behavioral responses. They may also provide some ear-specific information when insert earphones or headphones are not tolerated. Recent data suggest that DPOAEs provide evidence of whether or not there have been ototoxic changes in hearing when the highest DPOAE frequency with a robust response is used as the indicator (326,327). Widely used ototoxicity grading systems incorporating DPOAE and TEOAE do not currently exist and will need to be modified from threshold level–based systems. It is important to recognize that both DPOAE and TEOAE are exquisitely sensitive to middle ear dysfunction (328–331), and cannot be reliably used to determine ototoxicity without a normal tympanogram. Nonetheless, DPOAE and TEOAE have been found to be helpful for early detection of ototoxicity and can remain useful components of the monitoring evaluation (317,323,332–338).

The most widely used criteria to detect ototoxic change are the 1994 ASHA criteria (339), while the most widely used criteria to report adverse events in hearing are the National Cancer Institute Common Terminology Criteria for Adverse Events, Ototoxicity Grades (340) for adults, and Brock's Hearing Loss Grades in children (341). However, inconsistencies have been noted in these classification systems and it has also been demonstrated that these systems are not sensitive to obvious clinical differences in hearing loss in adult patients (276), and underreport and minimize the clinical significance of the hearing loss in children (48). Newer grading systems that more accurately characterize the clinical and functional significance of ototoxicity as specifically related to the need for intervention with assistive hearing devices have been proposed (37). As we enter a new age of otoprotective agents and strategies, coupled with greater understanding of genetic factors implicated within ototoxicity, it becomes ever more essential to develop robust audiologic assessment and classification techniques in order to design good prospective clinical studies and report outcomes in an accurate fashion (342,343).

HIGHLIGHTS

- A large number of systemic and topical agents can cause functional impairment and cellular damage to the inner ear.
- Symptoms of ototoxicity include hearing loss (primarily high frequency), tinnitus, and balance impairment.
- The most commonly used drugs causing ototoxicity are the aminoglycosides and platinum-containing chemotherapy agents.
- Topical agents are potentially ototoxic when used in the ear; therefore, nonototoxic fluoroquinolones are recommended when there is communication (e.g., open perforation, patent tube) between the ear canal and the round window membrane.
- The A1555G mutation in mitochondrial 12S rRNA gene results in significantly increased susceptibility to aminoglycosides.
- Genetic variants of TPMT and COMT are significantly associated with cisplatin-induced ototoxicity.
- A number of antioxidants such as N-acetyl-cysteine and sodium thiosulfate have been shown to protect against ototoxicity. These otoprotective agents are hypothesized to lower toxic levels of ROS thus diminishing cell death mechanisms.
- Modalities to monitor ototoxicity include standard pure-tone audiometry, HFA, and OAEs.

159 Cerebellopontine Angle Tumors

Matthew L. Bush *D. Bradley Welling*

INTRODUCTION

The cerebellopontine angle (CPA) is a complex and well-guarded anatomic region of the cranial base that contains an intricate interface of the central and peripheral nervous systems. Lesions occurring within this area are diverse in etiology and may lead to significant symptoms. The otolaryngologist frequently encounters pathology of the CPA that may present a diagnostic and therapeutic dilemma. A thorough knowledge of the anatomy of the region along with a clear understanding of diagnostic and therapeutic options for tumors in this region is vital for successful management. A variety of lesions may occur in this location and the differential diagnosis is discussed.

History

Tumors occurring within the CPA were identified as early as the late 1700s (1); however, little was known about the anatomy of this region and even less was known about the physiology of the nervous system. During the 1800s, Sir Charles Bell, a surgeon and skilled anatomist, carefully documented the intricate anatomy of the brainstem and cranial nerves, and he is credited with publication of the first clinical case of a CPA tumor in 1833 (2), which was identified as a vestibular schwannoma. The first successful removal of CPA vestibular schwannoma was performed by Sir Charles Ballance in 1894; however, surgical intervention for CPA tumors carried a mortality rate near 80% (3).

Significant advances in diagnostic evaluation of brain tumors occurred during the late 1800s and early 1900s, which allowed further correlation of clinical symptoms with specific lesions (4). Subsequently, the term cerebellopontine angle tumor was introduced in 1902 (5) to describe posterior fossa tumors. With the aid of radiographic imaging and astute clinical observation, Harvey Cushing carefully described the CPA syndrome in his 1917 monograph, *Tumors of the Nervus Acusticus and the Syndrome of the Cerebellopontine Angle* (6). Furthermore, Cushing advocated surgical intervention for CPA tumors to prevent brainstem compression and death via a suboccipital craniotomy approach to facilitate subtotal tumor removal. Mortality rates for surgical intervention dropped below 30%. Walter Dandy (7) advocated complete resection of CPA tumors through a modified suboccipital approach that improved exposure through resection of the lateral third of the cerebellum.

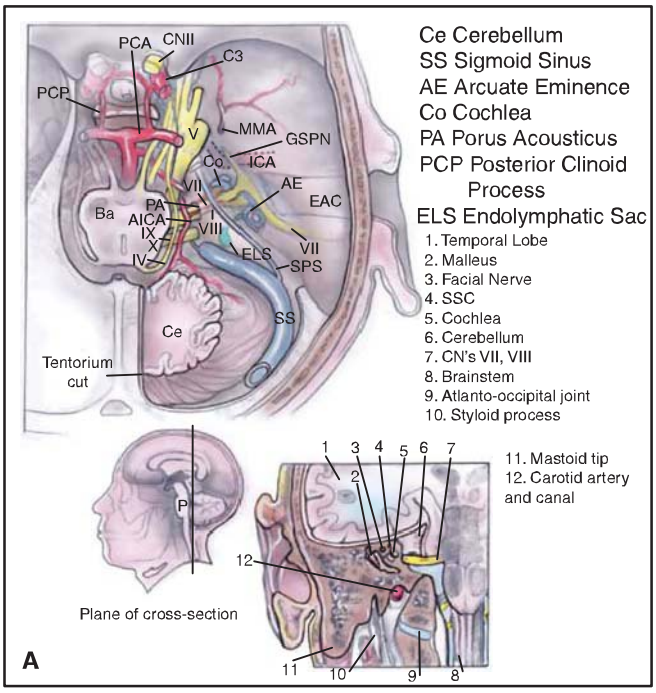
The latter half of the 20th century led to further advances in cranial base surgery including improved imaging modalities, high-speed surgical drills, and the microscope. The translabyrinthine approach to the CPA, although previously described (8,9), was popularized by William House, who reported improved facial nerve function, tumor exposure, and reduced morbidity and mortality. In an attempt to preserve hearing, House also advocated and demonstrated the utility of the middle fossa approach in small intracanalicular tumors (10,11). Although surgical approaches to the CPA have changed little over the past several decades, technologic advances in microsurgery, stereotactic radiation, diagnostic evaluation, and perioperative care have continued to reduce morbidity and mortality.

Anatomy

The CPA is a subarachnoid space filled with cerebrospinal fluid (CSF) and contains tortuous brainstem vessels and cranial nerves (Fig. 159.1). This inverted triangular-shaped space within the lateral posterior fossa is bound superiorly by the cerebellar tentorium and inferiorly by the cerebellar tonsil. The ipsilateral cerebellar hemisphere and the brainstem form the posterior and medial borders, respectively. The posterior face of the petrous temporal bone, with its dural reflection, forms the anterior border. The CPA cistern is the space between the pons, medulla oblongata, and the

cerebellum medially and the temporal bone anteriorly. It contains blood vessels, cranial nerves, and the cerebellum flocculus and choroid plexus, which are surrounded by CSF. This cistern extends into the medial aspect of the internal auditory canal (IAC) of the petrous bone, which is known as the porus acusticus. Within the superior portion of the cistern, the trigeminal nerve travels from the lateral pons to the Meckel cave. The seventh and eighth cranial nerves exit the brainstem at the lateral pontomedullary junction adjacent to the foramen of Luschka and travel prominently within the CPA and then enter the porus acusticus. Inferiorly, the ninth, tenth, and eleventh cranial nerves extend from the medulla across the inferior lateral aspect of the CPA and enter the pars nervosa of the jugular foramen. The basilar artery lies near the midline anterior to the brainstem and gives off the anterior inferior cerebellar artery (AICA), which takes a variable course through the CPA and can loop into the porus acusticus. Adjacent to the IAC, the AICA forms a branch, the labyrinthine artery, which travels laterally in the canal to supply the cochlea and labyrinth.

Within the cistern, the seventh and eighth cranial nerves lack an epineurium and are covered by pia mater and glial tissue. The facial nerve lies inferior and then anterior to



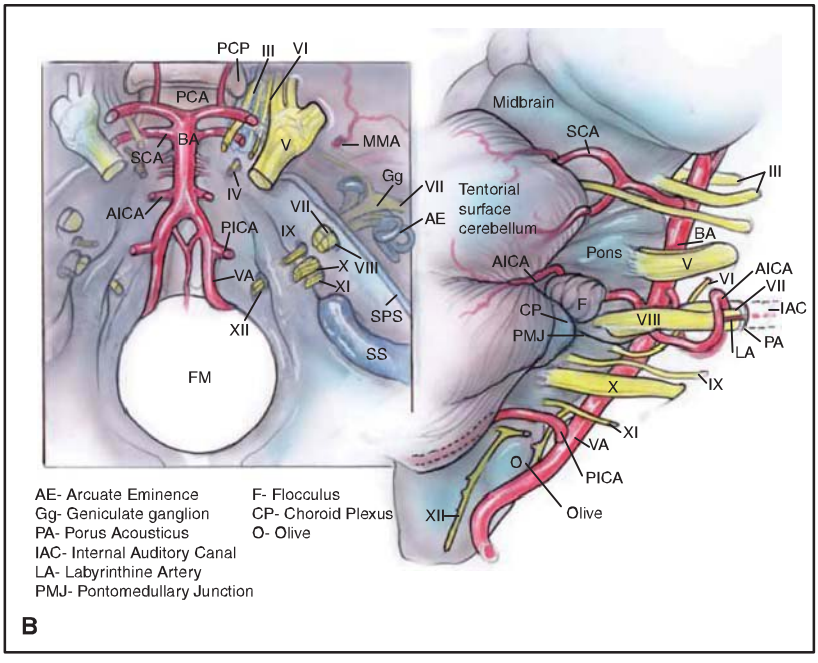


Figure 159.1 Axial and coronal **(A)** and sagittal views **(B)** through the skull at the level of the IACs and CPAs. V, trigeminal nerve; VII, facial nerve; VIII, cochleovestibular nerve; IAC, internal auditory canal. **(C)** Internal auditory canal contents.

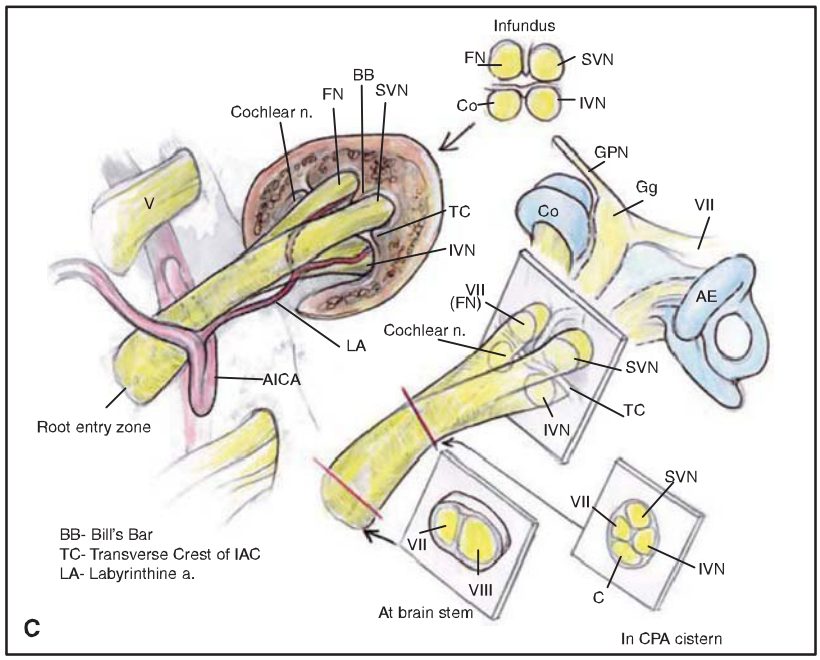

Figure 159.1 *(Continued)*

the vestibulocochlear nerve complex within the cistern but rotates 90 degrees as it travels within the IAC (Fig. 159.1C). Within the canal the eighth nerve divides into its main branches, and the superior and inferior vestibular nerves fill the posterior half of the canal. The cochlear nerve resides within the anteroinferior quadrant of the canal, with the facial nerve occupying the quadrant immediately superior to the cochlear nerve and anterior to the superior vestibular nerve. The lateral aspect of the IAC, known as the fundus, possesses bony partitions of the seventh and eighth cranial nerves. The vertical crest, also known as the Bill bar, separates the facial nerve from the superior vestibular nerve, while the transverse crest separates these two superiorly located nerves from the cochlear nerve and inferior vestibular nerve.

EXTRAAXIAL LESIONS

The differential diagnosis of CPA lesions can be categorized in multiple ways based on site of origin, imaging characteristics, or histopathology. Bonneville et al. (12,13) outlined a differential diagnosis strategy for CPA tumors based on site of origin. Under this classification, lesions are categorized as extraaxial, intraaxial, or skull base in origin. Extraaxial lesions are distinct from the brain parenchyma, displace surrounding structures, and may be neural, dural, vascular, inflammatory, or infectious in nature.

Vestibular Schwannoma

Epidemiology

Vestibular schwannomas are encapsulated benign tumors that arise from the Schwann cells of the vestibular nerve. Historically, these tumors have been referred to as acoustic neuromas; however, vestibular schwannoma represents a more accurate name. Vestibular schwannomas account for approximately 6% of all intracranial tumors and 85% of all CPA tumors (14). The incidence rate is variable globally but has been increasing over the past few decades and is reported to be 1.9 tumors per 100,000 people per year (15).

Histopathology

Vestibular schwannomas may occur on either the superior or inferior nerve; however, they more commonly originate from the inferior vestibular nerve (16,17). A commonly held misconception is that tumors most often develop at the glial–Schwann cell junction known as the Obersteiner-Redlich zone. Xenellis and Linthicum (18) point out that this is a much less common site of origin than laterally near Scarpa ganglion. Tumors typically grow slowly by expanding the porus and extending into the CPA (19). Grossly, the tumors appear yellow to gray; however, larger or cystic tumors may vary in appearance due to hemorrhage or necrosis. Approximately 5% to 20% of vestibular schwannomas are cystic in nature and tend to have poorer outcomes for facial nerve preservation (20,21). Vestibular schwannomas typically slowly expand within the IAC where they invade the vestibular nerves and eventually compress the cochlear and facial nerves, as well as the labyrinthine artery. Without intervention, this eventually leads to cochlear and vestibular dysfunction. The facial nerve is exceptionally resilient to dysfunction, in spite of compression and thinning of the nerve; nevertheless, facial weakness can be present in large tumors. Extension into the CPA can lead to compression of the cerebellum and brainstem and can cause cranial neuropathy, hydrocephalus, and even death.

Histologic examination of vestibular schwannomas reveals two discrete cell arrangements. Regions of compact spindle cells with bland cytoplasm and lack of nuclear atypia along with whorls of palisading nuclei aligned in rows (Verocay bodies) are referred to as Antoni type A arrangement. Antoni type B, however, possesses a less dense and more loosely arranged cellular histology. Areas of necrosis and fibrosis may also be seen within these tumors. Due to the neural crest cell origin of Schwann cells, schwannoma cells display strong S100 immunohistochemical staining.

Molecular Biology

Vestibular schwannomas most commonly occur sporadically; however, they can also occur as part of the genetic syndrome, neurofibromatosis type 2 (NF2). This highly penetrant autosomal dominant disorder with variable expressivity presents with multiple nervous system tumors. Diagnostic criteria have been defined for NF2 (22). The presence of bilateral vestibular schwannomas establishes a diagnosis of NF2. However, NF2 patients may also develop multiple spinal and cranial nerve schwannomas, meningiomas, and ependymomas. NF2 is caused by a germ-line mutation within a tumor suppressor gene, known as *NF2*, located on chromosome 22q12. This gene, identified by both Trofatter (23) and Rouleau (24), was found to encode a cytoskeletal protein known as merlin or schwannomin that modulates cellular adhesion, proliferation, and motility (25). A variety of mutations have been identified within the NF2 gene, and disease severity appears to be at least somewhat related to the type of mutation present (26), although marked phenotypic variation can occurs within NF2 families.

The absence of merlin results in alterations in cellular signaling and promotes cellular proliferation and tumorigenesis. Merlin typically interacts with tyrosine kinase receptors, such as the ErbB receptor family (27–31), to prevent growth; therefore, these receptors have been identified as potential targets for inhibition of proliferation in merlin-deficient vestibular schwannoma cells (32–36). Merlin also prevents the pro-growth effects of the AKT/PI3 kinase signaling pathway, and AKT activation has been demonstrated in vestibular schwannomas and may be another potential target for vestibular schwannoma drug development (37,38). Vascular endothelial growth factor (VEGF) and associated receptors have been implicated in vestibular schwannoma tumorigenesis, and NF2 patients have undergone clinical trials to inhibit tumor growth with anti-VEGF medications (39–42). Although translational research has advanced our knowledge of the mechanisms of tumor growth and has provided potential treatment targets, effective medical treatments have not yet been clearly demonstrated.

Clinical Presentation

Vestibular schwannomas, when small or when they arise in the CPA rather than the confines of the IAC, may be asymptomatic. More are being diagnosed incidentally on imaging studies performed for separate indications. The majority of tumors, however, present with unilateral auditory or vestibular dysfunction. Approximately 75% of patients with vestibular schwannomas experience unilateral tinnitus as an early symptom (43). This may be severe enough to affect quality of life (44,45). Unilateral hearing loss develops in approximately 95% of vestibular schwannoma patients (46) and typically is progressive in nature (47–49). Only 5% of patients with vestibular schwannomas present with sudden sensorineural hearing loss; however, 20% to 30% of vestibular schwannoma patients may experience a sudden deterioration in their hearing during their clinical course (50,51). This asymmetric hearing loss may respond to steroid treatment; however, further evaluation is indicated to rule out retrocochlear pathology. Vestibular schwannomas gradually ablate the function of the ipsilateral vestibular system; thus patients may experience disequilibrium, although this is the presenting chief complaint in only 10% of patients (52). Tumor extension into the labyrinth may result in episodic vertigo, similar to Meniere disease. A family history of vestibular schwannomas or NF2 should be determined. A thorough neurotologic examination is warranted for any patient with suspected cranial base pathology and should include a microscopic otologic examination, evaluation of cranial nerve function, and cerebellar examination. Decreased sensation of the ear canal and conchal bowl is referred to as Hitselberger sign and is due to dysfunction of the sensory component of the facial nerve by an expanding vestibular schwannoma. Expansion of the tumor within the CPA may lead to brainstem compression and cranial nerve dysfunction and present with diplopia, facial hypesthesia, facial paralysis, dysphagia, hoarseness, hydrocephalus, and, potentially, death (45,52).

Diagnostic Evaluation

Audiologic Behavioral and Electrophysiologic Evaluation

Audiometric evaluation of hearing loss is fundamental to the evaluation of patients with vestibular schwannomas and includes, at a minimum, pure-tone audiometry and word discrimination evaluation. Patients with vestibular schwannomas typically present with unilateral sensorineural hearing loss with disproportionate asymmetric word recognition. Even when hearing loss is mild, vestibular schwannoma patients typically experience a significant degree of word recognition dysfunction. In order to report outcomes consistently, auditory function should be documented using the American Academy of Otolaryngology—Head and Neck Surgery classification (53). Acoustic reflex threshold and acoustic reflex decay have been used as a screening tool for retrocochlear pathology, but these tests are not commonly employed currently. Auditory brainstem response (ABR) may be useful for electrophysiologic assessment of auditory function. An interaural wave

V latency difference of greater than 0.2 ms, or prolonged interpeak latencies greater than 4.4 ms for I–V, 2.3 ms for I–III, or 2.1 ms for III–V raise the suspicion of a vestibular schwannoma. ABR usage is limited by the fact that a reliable waveform is absent in patients with moderately severe hearing loss. The sensitivity of ABR is greater than 90% in medium and large tumors; however, the sensitivity ranges between 60% and 80% in tumors less than 1 cm (54–56). The sensitivity of ABR has been increased to 95% with the use of a stacked ABR technique as reported by Don et al. (57).

Vestibular Assessment

Progression of vestibular schwannomas leads to eventual loss of ipsilateral vestibular function, which is most often accompanied by central compensation. Videonystagmography (VNG) may document the degree of central and peripheral vestibular dysfunction. Caloric testing is the most useful component of VNG testing in vestibular schwannoma patients, and it may identify a unilateral vestibular weakness in tumors that have affected or originate from the superior vestibular nerve. A small schwannoma of the inferior vestibular nerve may have a normal caloric response and VNG entirely. It has been suggested that VNG may add prognostic information by identifying the nerve of origin when a hearing preservation operation is considered.

Evaluation of the inferior vestibular nerve can be performed with vestibular evoked myogenic potential (VEMP) testing, which may further assist in determining the nerve of origin. A VEMP is elicited by stimulating the saccule through a high-intensity sound stimulus. Excitation through the vestibulospinal central tract leads to a biphasic reflex potential from the ipsilateral sternocleidomastoid muscle. Patients with inferior vestibular nerve tumor commonly have an absent or reduced VEMP response when the caloric testing may be normal (58,59); however, VEMP responses may be normal in the presence of an inferior vestibular nerve tumor. It is likely that the presence of a VEMP response is more closely related to the size and ensuing neural compression of a tumor within the IAC than by the nerve of origin (60).

Imaging Studies

Advancements in radiographic imaging modalities continue to improve the diagnosis of CPA tumors. Small tumors can be diagnosed with high sensitivity. Magnetic resonance imaging (MRI) is the gold standard in evaluation of patients with unilateral auditory and vestibular dysfunction. Noncontrasted T1-weighted images typically display vestibular schwannomas as hyperintense relative to CSF and iso- to hypointense to gray matter, while T2-weighted images show these tumors as hypointense to CSF and iso- to hyperintense to gray matter. These lesions typically have a component filling the IAC and may extend medially into the CPA having an "ice cream cone" or "mushroom" appearance (Fig. 159.2). NF2 patients may develop large vestibular schwannomas that can compress the brainstem and cerebellum and lead to obstruction of the fourth ventricle (Fig. 159.3). Volumetric high-resolution T2 sequence can reveal the fluid-filled inner ear and tumor invasion into the labyrinth can be seen as a filling defect. T2 images can be useful in identifying hyperintense cystic regions within the tumor, while the solid portion of the tumor appears as a hypointense filling-defect within the CPA and/or the IAC. Additionally, the T2 images provide vital information regarding the lateral relationship of the tumor with the fundus of the IAC. CSF within the fundus of the IAC, adjacent and lateral to the tumor, is known as a "fundal cap," (Fig. 159.4) and its presence has been demonstrated to positively affect hearing preservation outcomes in middle fossa tumor resection (61).

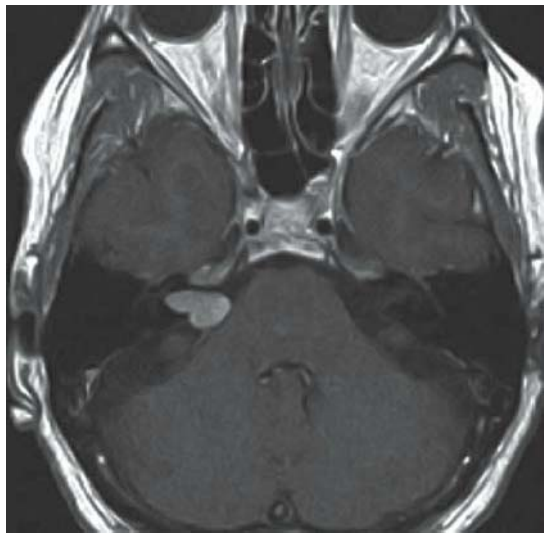

Figure 159.2 Axial T1-weighted contrast-enhanced MRI image at the level of the IAC demonstrating an enhancing right vestibular schwannoma with an "ice cream cone" or "mushroom" appearance.

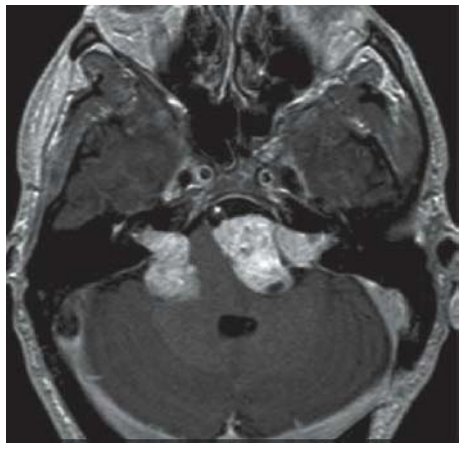

Figure 159.3 Axial T1-weighted contrast-enhanced MRI image at the level of the IAC demonstrating bilateral enhancing vestibular schwannomas with brainstem compression.

Figure 159.4 T2 fast spin-echo magnetic resonance image of a left intracanalicular vestibular schwannoma. Note the presence of CSF in the fundus lateral to the tumor.

The use of gadolinium-based contrast is standard in imaging of the CPA and the contrast-enhanced T1-weighted images of a vestibular schwannoma reveal marked tumor enhancement and can result in the detection of tumors as small as 1 to 2 mm. To reduce the expense of enhanced MRI some have advocated the use of noncontrast heavily T2-weighted fast spin echo (FSE) techniques. Comparisons of gadolinium-enhanced T1-weighted MRI with T2-weighted FSE sequences have demonstrated the reliability of T2 FSE sequences to detect mass lesions within the IAC and CPA and may be used as a screening tool for patients with sensorineural hearing loss or for those with contraindications to contrast administration (62,63).

Postimaging analysis and interpretation is vital in predicting outcomes and guiding clinical management. The standard documentation of tumor size is to record linear measurements in three dimensions; however, volumetric analysis of tumor size appears to be more sensitive in monitoring small changes of tumor growth over time (64). Prediction of hearing preservation following tumor resection has been shown to correlate with tumor volume (65).

Although MRI is the standard for diagnosis of vestibular schwannomas, patient movement causing motion artifact can limit the study resolution. Patients may not be able to tolerate the close confines of the MRI; however, mild sedatives or open MRI units may improve patient compliance. Due to the strong magnetic field, the presence of certain metallic foreign bodies or implants is a contraindication of MRI. The safety of MRI in patients with otologic or cochlear implants has been debated and concern has been raised for implant heating, malfunction, and/or displacement. Some early stapes prostheses were made with ferromagnetic materials that would, potentially, be unsafe in an MRI. Currently, most stapes prostheses are considered safe for 1.5-Tesla magnet of MRI (66,67). NF2 patients face bilateral hearing loss and may undergo placement of cochlear or auditory brainstem implantation for rehabilitation; yet, they have a lifelong need for serial imaging. If implant magnets are removed, these patients can undergo MRI safely. Although not FDA approved, Crane et al. (68) suggest that cochlear implant patients can safely undergo MRI with the receiver magnet left in place, as long as the device is bound tightly by head wrapping prior to scanning in a low field strength magnet.

Computed tomography (CT) scanning is not ideal for CPA examination but may be used in patients who cannot undergo MRI. One-millimeter CT scanning in both the axial and coronal planes provides excellent detail of the temporal bone and IACs. Expanding vestibular schwannomas may lead to expansion of the IAC, which may be demonstrated on CT. The soft tissue resolution of CT scan, even with contrast administration, is inferior to MRI and tumors less than 1 cm can be missed on CT (69). Tumors that cause erosion of the otic capsule or large tumors that extend into the CPA and compress the brainstem are readily visible on CT. Historically, air-contrast was administered through a lumbar puncture to increase the sensitivity of CT to localize intracanalicular tumors.

Treatment Options

When considering treatment options for patients with vestibular schwannomas, the utmost priority is preservation of the patient's life, which is then followed in priority by preservation of brainstem and facial nerve function. Hearing preservation is an important objective; however, patients may be rehabilitated following the loss of hearing with contralateral routing of signals (CROS) type of hearing aids or bone-anchored devices.

Patients with vestibular schwannomas are faced with three primary treatment options: observation with serial imaging, stereotactic radiation, and microsurgical excision. Factors that affect treatment decision include patient preference, patient age/medical health, tumor size and location, auditory and vestibular function on the tumor and contralateral side, and tumor progression. The skill and experience of the treating team should also be considered. Because of the dearth of high-quality outcomes studies, patients must choose from these several options when deciding on how to manage their tumor.

Observation

Because vestibular schwannomas are most often slow-growing tumors, observation with serial imaging is recommended in 25% to 30% of our patients. At the time of diagnosis, the rate of tumor growth is unknown and somewhat unpredictable. Rates of tumor growth range widely in the literature, but meta-analyses indicate that at least 50% of vestibular schwannomas exhibit growth and growth

ranges from 0.25 to 3.2 mm/y (70–72). In our patients, 66% demonstrated volumetric growth over an average follow-up of 3 years. Interestingly, NF2-associated vestibular schwannomas had an independent protective effect against deterioration of the pure tone average (73). NF2-associated vestibular schwannomas have been shown to exhibit a growth rate of 1.3 mm/y (74). Identification of predictors of tumor growth has been limited; however, patients that are younger, experience tinnitus initially, have large tumors at the time of presentation, have cystic tumors, or experience significant growth during the first year after diagnosis are more likely to have persistent tumor growth (75–77). If observation of the vestibular schwannoma is selected as the clinical path, the first follow-up MRI is recommended at 6 months and yearly thereafter if no growth is detected with volumetric measurements. Tumors may exhibit significant variability in growth and may experience precipitous increases in size with significant morbidity and even mortality (78,79); therefore, observation carries inherent risk.

Observation may allow enough time to determine the tumor growth characteristics, and if no growth is demonstrated, then no treatment may ever be necessary. If symptoms change or tumor growth is seen, then patients may undergo intervention when appropriate. If hearing is present at the time of tumor discovery, the most likely complication of observation is a decline in auditory function during the observation period. The opportunity for hearing-preservation approach may be lost. Observation is a reasonable option for patients who do not have significant brainstem compression or when the tumor affects an only-hearing ear. We are inclined to recommend observation when the patient is over 65 years of age, or if they are in poor medical health. Patients' preference certainly plays a role. In spite of the unpredictability of tumor and associated symptoms, observation may afford years of residual auditory function without the risk of radiation or surgery.

Stereotactic Radiation

Pioneered by the Swedish neurosurgeon, Lars Leksell, in the 1950s, stereotactic radiation therapy has become a vital tool in the management of a wide variety of intracranial pathology. Intracranial stereotactic radiation therapy involves the administration of radiation to a precise location so as to induce radiation damage to the target area and minimize the effect to the adjacent structures. Current modalities for radiation for vestibular schwannoma include single fraction gamma radiation therapy from an active cobalt-60 source (Gamma Knife), fractionated radiation, hypofractionated linear accelerator photon radiation therapy (XKnife, CyberKnife, Trilogy, Novalis, and SyngergyS), and proton beam. The term "radiosurgery" is commonly employed to describe the precision of such radiation; however, it is a misnomer since it involves no surgery and the radiation is delivered to a closed intracranial lesion. Vestibular schwannomas are treated with a highly conformal prescribed dose of radiation under the direct supervision of a radiation treatment team, which typically consists of a surgeon (neurosurgeon or neurotologist), a radiation oncologist, and a physicist.

The goals of stereotactic radiation therapy are to provide the lowest effective dose of radiation that induces long-term tumor growth control without subjecting patients to the risk of surgical intervention and to prevent acute loss of neurologic function. The technique for stereotactic radiotherapy varies depending on the modality used. For gamma knife, patients undergo head frame placement with pretreatment MRI and/or CT imaging, which are then uploaded to the radiation dose–planning computer where the images can be examined for inaccuracies and appearance of the pathology. Both CT and MRI studies can be fused to accentuate the lesion and the surrounding structures. The margins of the tumor are outlined and then the treatment team proceeds with dose planning to contour the treatment dose to the tumor with a sharp radiation dose drop-off at the margins of the tumor (Fig. 159.5). Once all members of the team confirm the treatment plan and dose, patients are placed in the treatment suite and the head frame is immobilized on the table and advanced into the unit for treatment. The gamma knife dose used to treat vestibular schwannomas is, generally, between 12 and 13 Gray (Gy) to 50% isodose line at the periphery of the tumor to maximize tumor effect and minimize complications (80–82). The computer software calculates the time and exact positioning of the patient within the unit to achieve the treatment dose. Linear accelerators differ, in that patients do not require head frame placement or rigid fixation and they are fitted with a mask that provides immobilization. A series of real-time radiographic images are obtained during treatment to confirm correct positioning and to provide guidance during the treatment. CyberKnife treatment doses vary significantly but, typically, a total of 18 Gy is delivered over three fractions and has been reported to be safe and effective (83). Following stereotactic radiotherapy,

Figure 159.5 Axial T1-weighted contrast-enhanced MRI image at the level of the IAC demonstrating an enhancing right vestibular schwannoma with a conformal stereotaction radiation treatment dose plan outline.

the head frame is removed, patients are observed for a few hours and then they are discharged home. Serial MRI images are obtained over the patient's lifespan to monitor for persistent tumor growth.

Outcomes for tumor growth control and neurologic preservation vary greatly in the literature and lack uniform reporting (84). Additionally, many vestibular schwannomas do not grow over the course of time, which makes the assessment of the true efficacy of treatment difficult to determine. Nevertheless, patients who have had stereotactic radiotherapy have reported growth control rates of 90% to 100% (85–102) for gamma knife and 98% for CyberKnife (83). NF2 patients treated with gamma knife have reported actuarial tumor control rates of 71% to 85%, within declining rates with longer follow-up (103–105), while data on CyberKnife treatment of NF2 patients is limited, but has been reported to have over 90% tumor control rate in a small group of patients with short follow-up (less than 25 months) (106).

Stereotactic radiotherapy is an attractive option for many patients and has the benefit of no hospitalization and the rapid return to normal activity and work almost immediately after treatment. This treatment is indicated for those who have demonstrated tumor growth, are elderly, or have medical contraindications to microsurgery. Radiation lacks the microsurgical risks of infection and CSF leak. A wide variety of protocols have been reported that generally recommend treatment of tumors that measure less than 2.5 to 3 cm. Stereotactic radiation also is a valuable tool to treat tumor recurrence following microsurgery (107). Patients who have radiation treatment of their vestibular schwannoma rarely experience complete resolution to the mass; therefore, they are faced with a need for prolonged surveillance with repeat MRI during the course of their life.

Preservation of neurologic function is a primary goal of stereotactic radiotherapy; however, the development of adverse side effects is directly related to radiation dose. Complications of stereotactic radiotherapy are similar to microsurgical resection. Hearing loss may occur acutely following radiation, but, typically, hearing loss occurs gradually months to years later. Hearing preservation outcome reporting lacks uniformity (84); but is reported to range from 50% to 86% (108,109). This hearing loss has been linked to radiation of the cochlea and maintaining a cochlear dose less than 6.9 Gy is important in preserving residual hearing (110,111). The actuarial serviceable hearing preservation rates of NF2 patients has been reported at 73%, 59%, and 48% for 1, 2, and 5 years, respectively (105).

Facial and trigeminal cranial neuropathies due to radiation treatment are similar in incidence and are reported around 0% to 5% in sporadic vestibular schwannomas and 8% in NF2 patients; however, these rates increase with doses greater than 13 Gy (112,113). Hemifacial spasm may also occur in 2% to 4% and may be related to a delayed insult to the facial nerve (114,115). Hydrocephalus without evidence of tumor growth may occur in up to 5% of patients and is more common in patients with larger tumors that are treated with radiotherapy and may be related to proteinaceous debris obstruction of CSF flow (116,117). Chronic vestibular dysfunction may be present in 13% to 26% of patients following stereotactic radiotherapy (114,118). Radiation has been reported to cause fibrosis of the facial nerve leading to poorer facial nerve outcomes if microsurgical resection is necessary following radiotherapy (119,120). Others, however, have reported no significant changes in facial nerve histology or functional outcomes (121). Malignant transformation and delayed oncogenesis, which is uniformly lethal, has been documented with stereotactic intracranial radiotherapy, and treatment with radiotherapy carries a 1:1,000 risk over a 5- to 30-year period (122–131).

Stereotactic radiotherapy remains a viable treatment option for patients with vestibular schwannoma. Irregularities in reporting outcomes have made it difficult to fully compare radiotherapy with microsurgical intervention. The long-term effect of radiation on tumor control and neurologic functions is not fully known and longitudinal follow-up will prove beneficial in informing patients and directing clinical management of vestibular schwannomas.

Microsurgery

Vestibular schwannomas have traditionally been treated with surgical management. Advances in microsurgical techniques and intraoperative anesthesia and monitoring have greatly reduced the morbidity and mortality in cranial base surgery. Collegial interaction and collaboration between neurosurgeons and neurotologist have greatly improved surgical management of these tumors and reduced complications. The primary surgical approaches—translabyrinthine, middle fossa, suboccipital (retrosigmoid), and combined—are described. Surgical intervention may involve complete resection, tumor debulking, or IAC decompression.

The surgical approach chosen to treat vestibular schwannomas is based on hearing function and tumor size and location. The surgery is performed under general anesthesia with neurophysiologic monitoring. In order to monitor the integrity of the facial nerve, long-acting paralytic should be avoided and facial EMG monitoring should be utilized during every procedure. Auditory function may be monitored with ABR or compound action potentials and may correlate with postoperative hearing preservation (132,133). Prophylactic doses of antibiotics along with one dose of intravenous dexamethasone are administered prior to incision. Generally, the goal for surgery is the complete resection of the tumor while preserving facial nerve and auditory function if present preoperatively. Hearing preservation can be accomplished through either

the middle cranial fossa or suboccipital approaches. As a general guide, we base selection of a hearing preservation approach upon the speech discrimination being greater than 70% and the tumor being less than 1.5 cm in diameter. These criteria are not absolute and patients with poor contralateral hearing or NF2 patients may be candidates even with marginal hearing. The middle fossa approach involves a temporal craniotomy for an approach to the IAC superiorly. The approach can be chosen to remove tumors that are limited to the IAC and are less than 1.5 cm (Fig. 159.6); however, larger tumors that extend into the CPA can be accessed by ligating the superior petrosal sinus and dividing the tentorium. This approach has reported hearing preservation rates of 80% to 90% (134–136) and has the benefits of no intradural drilling and low postoperative headache rates.

The suboccipital approach, historically, has been the primary approach to the CPA and is still the approach favored by many neurosurgeons. A craniotomy is performed inferior to the transverse sinus and posterior to the sigmoid sinus and then the cerebellum retracted to gain access to the posterior fossa. Because this approach offers wide exposure of the CPA, tumors of almost any size can be resected through this approach; however, access to the lateral aspect of the IAC is limited and may be a location for recurrence of tumor. Hearing preservation is feasible with this approach as well, but compression of the brainstem may obscure the root entry zone and lateral extension into the IAC may also complicate attempts to preserve the cochlear nerve. In order to preserve hearing, this approach is, ideally, used for tumors that are confined to the medial IAC and the CPA without brainstem compression (Fig. 159.7).

At present, the translabyrinthine approach represents the most commonly used approach to vestibular schwannomas in the CPA because there is often significant hearing loss prior to tumor diagnosis, and because it gives superior exposure of the facial nerve and less retraction of the cerebellum (Fig. 159.8). This approach involves a wide mastoidectomy, labyrinthectomy, and removal of posterior fossa dura medial to the sigmoid sinus. Due to the labyrinthectomy, hearing preservation is not an option with this approach. The facial nerve is encountered early in the dissection and this approach offers visualization of, almost, the entire course of the facial nerve. The exposure of the CPA is wide and cerebellar retraction is not necessary, with the exception of exceedingly large tumors.

The combined approach typically involves a suboccipital and translabyrinthine craniotomy and is utilized to facilitate exposure and resection of CPA tumors that are greater than 4 cm (Fig. 159.9). Extension of tumor anteriorly to the petroclival region may also employ the addition of a transcochlear approach; however, the facial nerve

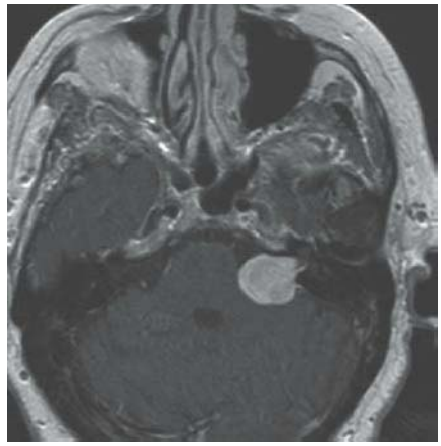

Figure 159.8 Axial T1-weighted contrast-enhanced MRI image at the level of the IAC demonstrating an enhancing left vestibular schwannoma suitable for either translabyrinthine or suboccipital microsurgical resection.

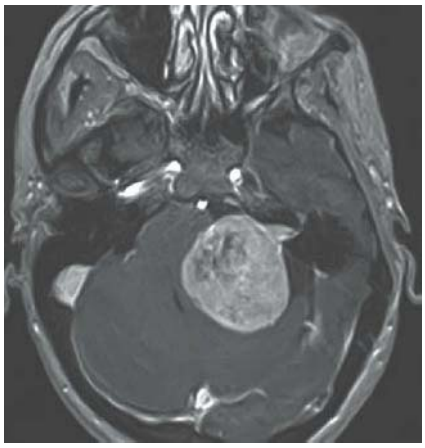

Figure 159.9 Axial T1-weighted contrast-enhanced MRI image at the level of the IAC demonstrating a large enhancing left vestibular schwannoma suitable for a combined microsurgical resection.

must be mobilized from the fallopian canal to facilitate this exposure. Hearing preservation is not feasible with combined approaches. The objective of this approach is for extensive debulking or complete resection of the tumor with decompression of the brainstem and the fourth ventricle.

Treatment planning for NF2 patients is a complex algorithm due to the complicated chronic nature of the disease. Since these patients are faced with the threat of deafness along with the loss of other special senses, preservation of hearing is vital and involves a proactive approach. Bilateral tumors also place the brainstem at greater risk of compression. Early detection and intervention may provide long-term functional hearing. Samii et al. (137) reported suboccipital resections in a series of NF2 patients and achieved total resection in 85%, preserved facial nerve anatomic integrity of 89%, and preserved useful hearing in 65% of patients. Slattery et al. (138) prefer the middle cranial fossa approach and reported 48% AAO-HNS class A hearing preservation and grade I/II facial nerve preservation in 81% of a series of pediatric patients. In NF2 patients with larger tumors, an auditory brainstem implant can be placed at the time of suboccipital or translabyrinthine tumor resection and may be utilized at a later time if the contralateral hearing declines. If the cochlear nerve can be preserved during translabyrinthine resection, cochlear implantation can be performed at the time of resection. Hearing rehabilitation is improved in patients with cochlear implants versus auditory brainstem implants, and cochlear implant patients possess higher open- and closed-set sentence understanding over time (139–141). In some NF2 cases in which hearing is declining and resection through a middle fossa approach in unlikely to preserve hearing; patients may be presented with the option of bony decompression of the IAC through a middle fossa approach. This approach does not involve any tumor removal but alleviates the pressure of the tumor on the cochlear nerve in the IAC and allows the tumor growth to progress superiorly into the middle fossa. This may prolong functional hearing in patients that face a bleak prognosis. Early and aggressive intervention is crucial to preserved function in NF2 patients.

Middle Cranial Fossa Approach (Fig. 159.10)

As with all cranial base cases, the bed is rotated 180 degrees from the anesthesia team and facial nerve monitor electrodes are placed in the orbicularis oris and orbicularis oculi, and the integrity of the monitor is confirmed. The middle cranial fossa approach involves turning the patient's head toward the opposite the side of the lesion. The surgeon is classically seated at the head of the table with the assistant on the side of the lesion and the microscope base positioned at the opposite side of the lesion. Microscopes with a long suspension arm may be positioned behind the surgeon and brought over their head. Mannitol (0.5 to 1.0 g/kg) is given intravenously at the onset of the procedure and the CO_2 level is decreased to 25 to 28 mm Hg as the dura is approached to decrease intracranial pressure.

Following shaving, prepping, and sterile draping of the preauricular region, a skin incision is created extending 1 cm anterior to the tragus and then extending 12 cm superiorly toward the vertex of the scalp. The temporalis fascia and muscle are divided and the periosteum is widely elevated. The root of the zygoma is identified as a reference point and a craniotomy is centered on this point. A 4 cm by 4 cm craniotomy is outlined at this point and then carried out with an otologic drill or craniotome with footplate shoe. The craniotomy window extends 2 cm anterior and 2 cm posterior to the zygomatic root and the inferior rim of the craniotomy should be located immediately superior to the zygomatic root so that the floor of the middle fossa will be easily visualized. Once the bone flap is freed from the dura it is placed on the back table and will be replaced at the conclusion of the case. Exposed air cells of the mastoid or zygomatic roof are sealed with bone wax to prevent a postoperative CSF leak.

Under microscopic visualization, the temporal dura is gently elevated from the floor of the middle fossa, which is performed in a posterior to anterior direction to prevent avulsion of the greater superficial petrosal nerve. The geniculate ganglion can be dehiscent on the middle fossa floor and care should be taken not to incur trauma to this area. Anteriorly, care must be taken not to lacerate the middle meningeal artery. A meningeal venous plexus is commonly encountered anteriorly, which can cause significant bleeding, but is usually controlled with packing. The medial extent of dural elevation is the superior petrosal sinus. The arcuate eminence and greater petrosal nerve are identified. The greater petrosal nerve can be stimulated with the facial nerve stimulator probe with a 0.1 to 0.3 mA stimulus. The House-Urban middle fossa retractor is placed in position to gently retract the dura during the IAC

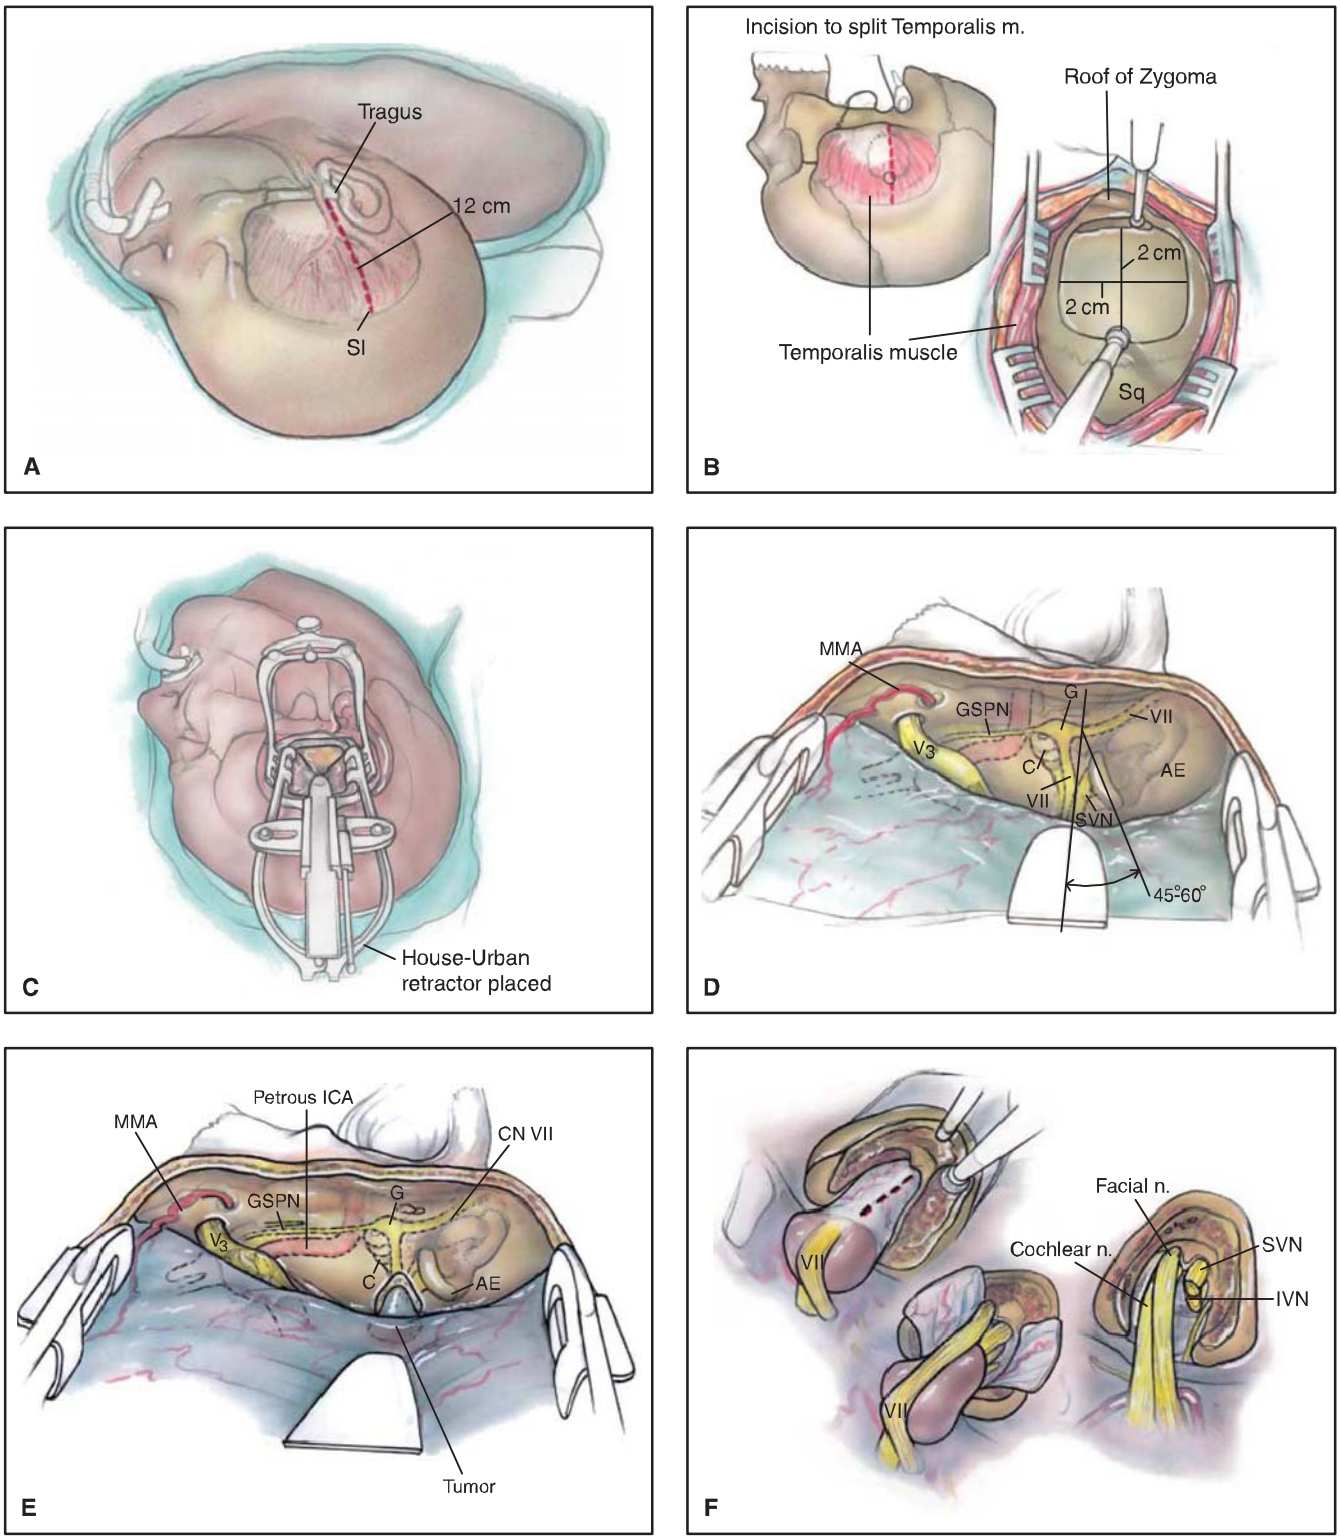

Figure 159.10 Middle fossa approach. **A** and **B:** A 12 cm incision is followed by a 4 x 4 cm craniotomy. **C:** The retractor is positioned so that the structures of the temporal bone can be identified. With the greater superficial petrosal nerve and the arcuate eminence as guides, bone removal is begun and the IAC is identified. **D:** The dura then can be incised away from the facial nerve under high magnification. **E:** The internal auditory canal is identified. **F:** The dura is opened sharply avoiding the facial nerve. Fine hooks are used to separate the superior vestibular nerve from the facial nerve. The IAC is filled with fat. TL, temporal lobe; GSPN, greater superficial petrosal nerve; ICA, internal carotid artery; BB, the Bill bar; VII, facial nerve; SV, superior vestibular nerve; T, tumor; M, malleus; I, incus; SSC, superior semicircular canal; AE, arcuate eminence; G, geniculate ganglion; C, cochlea; MMA, middle meningeal artery. *(Continued on next page)*

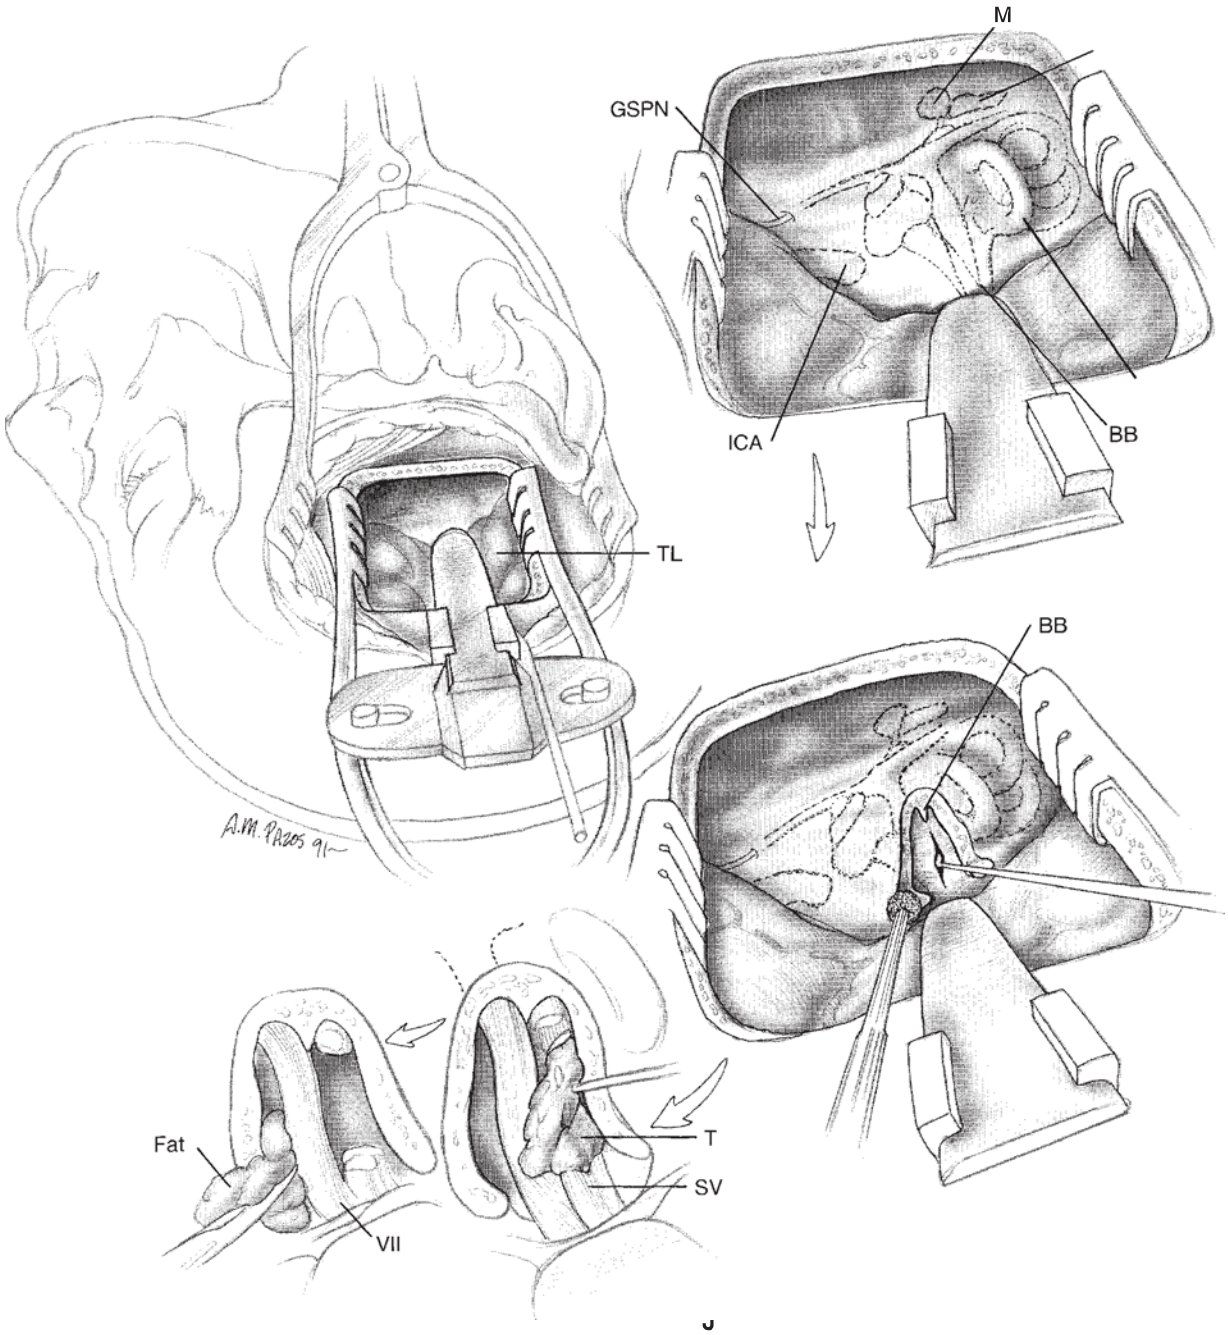

Figure 159.10 *(Continued)*

drilling and tumor resection. The location of the superior semicircular canal is confirmed by carefully thinning the bone of the arcuate eminence. The meatal plane is the approximate location of the IAC and is defined by the bisection of the angle between the superior semicircular canal and the greater superficial petrosal nerve. The bone surrounding the IAC is removed with small diamond burrs exposing approximately 180 degrees around the canal. The medial and lateral borders of dissection are the porus and vertical crest, respectively. Extreme care should be taken to avoid fenestration of the cochlea anteriorly and exposure of the labyrinthine section of the facial nerve, which rises to form the geniculate ganglion near the middle fossa floor surface.

Once the dura is widely exposed, the posterior aspect of the dura is sharply incised and reflected anteriorly. The facial nerve is identified with the stimulator set on 0.05 mA. The facial nerve and the tumor are gently separated laterally and this plane of dissection is followed medially. The tumor is dissected from the cochlear nerve in a medial to lateral direction to prevent avulsion of the cochlear nerve from the fundus. Once this plane has been established and the tumor is free from the cochlear nerve, the superior vestibular nerve and the tumor can be

avulsed from the fundus. The inferior vestibular nerve is often avulsed from the fundus as well and removed with the tumor. Once the intracanalicular tumor has been freed from the cochlear and facial nerve the medial border is identified. The medial normal vestibular nerve is sharply transected. Again, the integrity of the facial nerve is confirmed with a 0.05 mA stimulus and the IAC is occluded with a plug of temporalis muscle. Fat may also be used to occlude the IAC and may make distinguishing recurrent tumor easier on postoperative MRI. Once the retractor is removed, the dura and temporal lobe are allowed to resume their native position. The bone plate is replaced and may be fixed in position with titanium plates and screws. The wound is closed in multiple layers in watertight fashion, and a compression dressing is applied.

Suboccipital Approach (Fig. 159.11)

Positioning and setup for the suboccipital approach is similar to the other approaches, with the exception that the patient is placed in Mayfield pinions with the chin slightly tucked, the head turned laterally, and the neck slightly extended. Other options included the park bench position and the seated position. The seated position offers better visualization due to gravitational drainage of blood or fluid inferiorly; however, the risk of air embolism and lumbar disk rupture exists. Similar to the middle fossa approach, intracranial pressure is decreased with hyperventilation and intravenous mannitol.

A curvilinear incision is created approximately four fingerbreadths posterior to the postauricular crease. The incision carried down to and through the periosteum of the skull. The periosteum is widely elevated and cervical musculature attachments to the skull base are divided with electrocautery. A 4 cm by 4 cm craniotomy is then created posterior to the occipitomastoid grove, and the bone flap is placed on the back table to be replaced at the conclusion of the case. The superior and anterior borders of the craniotomy are the transverse and sigmoid sinuses, respectively. Inferiorly, bone removal can be extended to open the foramen magnum; however, care must be taken not to injure the vertebral artery as it emerges laterally from foramen transversarium.

A cruciate or "U"-shaped dural incision is performed and the dural edges are retracted with silk sutures. A nonadhesive protective collagen or gelatin sponge is placed on the lateral surface of the cerebellum to prevent desiccation. The cerebellum is gently retracted to allow egress of CSF. Placement of cottonoid strips inferiorly for 10 to 15 minutes may wick CSF effectively if elevated intracranial pressure prevents cerebellar manipulation.

Once the pressure decreases, gentle retraction of the cerebellum allows visualization of the CPA. Bands of arachnoid can be divided sharply to facilitate CPA exposure. A retractor is placed to allow full visualization of the posterior face of the tumor. The facial nerve monitor stimulating probe should be passed over the posterior face of the tumor to ensure that the facial nerve has not been displaced posteriorly. For large tumors, the posterior tumor capsule is cauterized and incised. The internal contents of the tumor are removed to facilitate circumferential extracapsular dissection. The capsule is dissected free from the cerebellum and brainstem, and the seventh and eighth nerves are identified at their root entry zone. Small tumors should be dissected away from the facial and cochlear nerves at this point.

Prior to removing the bone from the posterior IAC, cottonoid sponges or pledgets of Gelfoam are placed within the CPA to prevent bone dust dispersion. The dura overlying the posterior petrous bone is removed and small diamond burrs are utilized to the remove the posterior lip of the IAC. The posterior semicircular canal and vestibule in the otic capsule are the lateral extent of bone removal. Preoperative MRI imaging can aid in measuring the limits of lateral bony dissection. Once the dura of the IAC is exposed, it is then sharply incised. The superior and inferior vestibular nerves along with the tumor are identified and retracted inferiorly to expose the facial nerve, which is confirmed with the facial nerve stimulator. The tumor and vestibular nerves are gently avulsed from the fundus and dissected from the facial and cochlear nerves. The preferred direction of dissection is from medial to lateral to avoid avulsion of the cochlear nerve. Final tumor resection at the fundus may need to be completed in a medial to lateral fashion. The dissection around the porus continues from a lateral to medial direction until joining the dissection plane of the CPA. The medial vestibular nerves adjacent to the root entry zone are sharply divided and the tumor can be removed. A 30-degree endoscope can be used to examine the lateral IAC for any residual tumor. Special attention must be given to protect the labyrinthine artery in hearing preservation cases.

Following tumor removal, the wound is irrigated and the sponges are removed. The edges of craniotomy are inspected and air cells are sealed with bone wax. The dura is reapproximated and closed in a watertight fashion with silk suture. The bone plate is replaced and can be fixed in position with cranioplasty low-profile titanium plates and screws. The muscle and skin are closed in multiple layers in watertight fashion and a pressure dressing may be applied.

Translabyrinthine Approach (Fig. 159.12)

The translabyrinthine approach is performed with the patient in the supine position with the head turned away from the operative site. The surgical assistant is opposite the surgeon, and the microscope base is brought in at the head of the table. Once the facial nerve monitor is set up, the postauricular region is shaved, prepped, and draped in the usual fashion. Additionally, the abdominal left lower quadrant is prepared and draped for harvest of a free abdominal adipose graft for closure of the cranial base defect. The left is typically used so as to prevent confusion with an appendectomy scar.

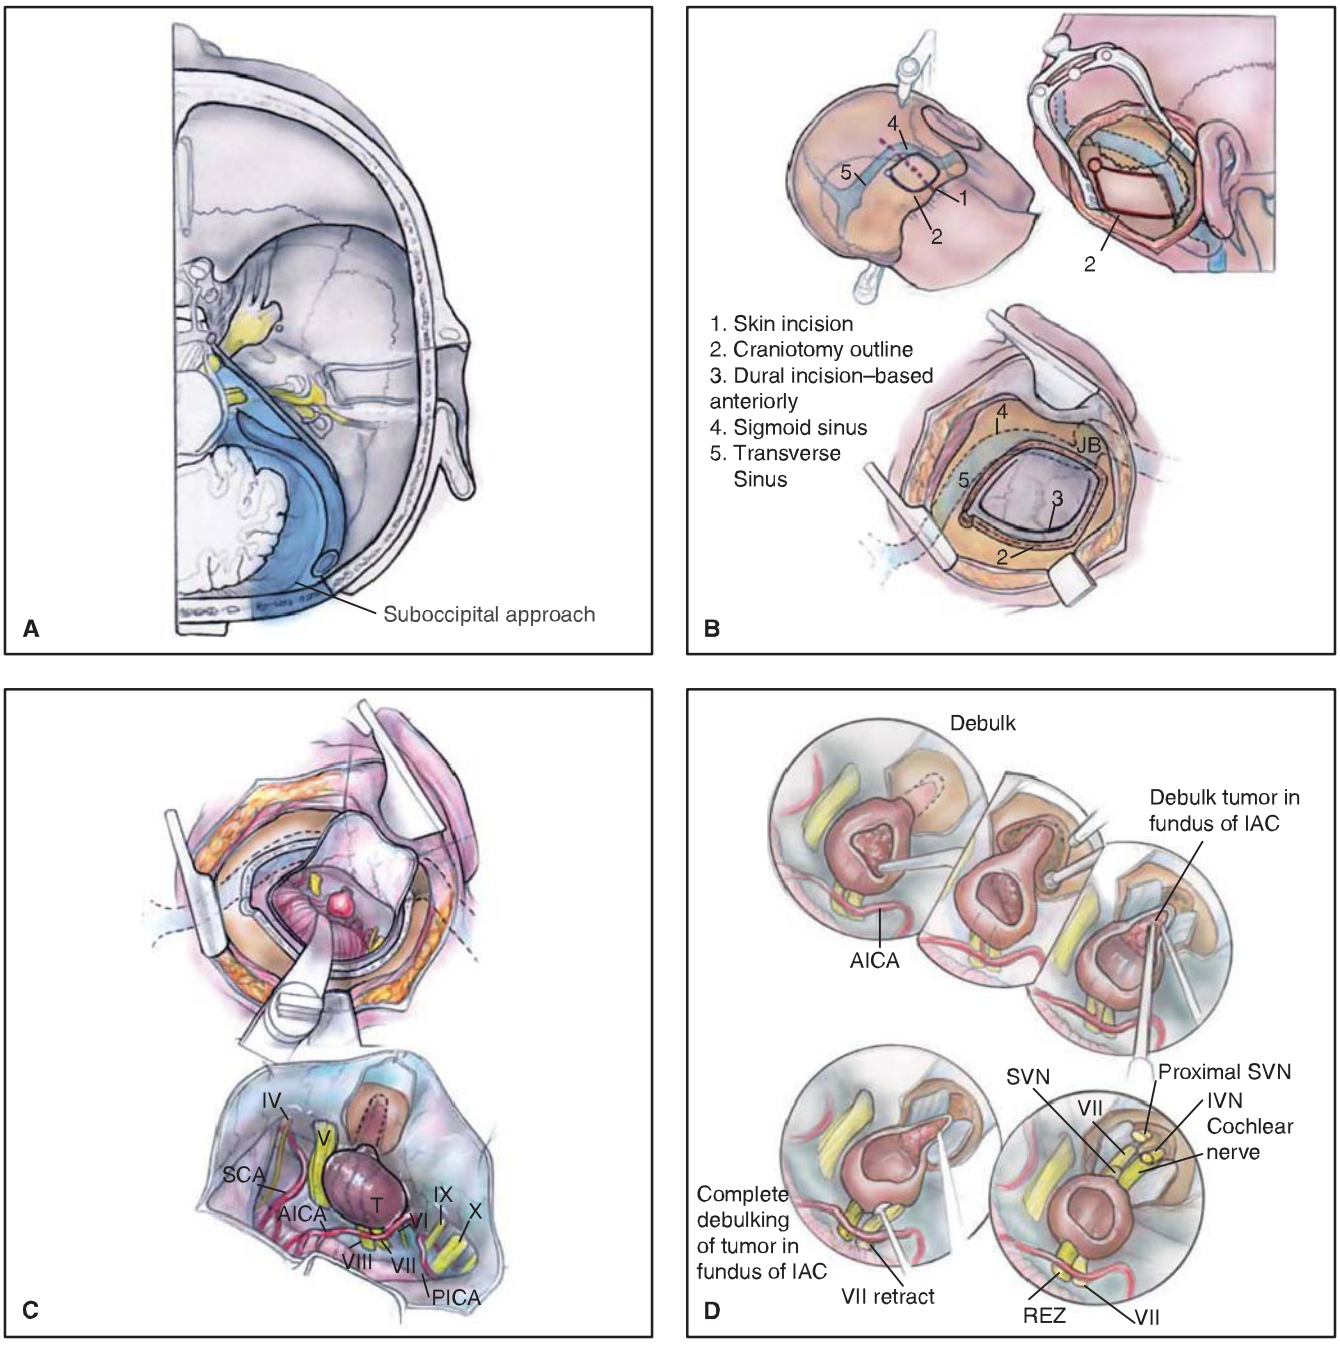

Figure 159.11 Retrosigmoid–suboccipital approach. **A:** The approach between the posterior temporal bone and cerebellum is outlined in blue. **B:** A 3 × 3-cm craniotomy is made with the cutting bur, the sigmoid sinus serving as the anterior limit and the transverse sinus as the superior limit. **C:** The cerebellum is retracted exposing the tumor and the internal auditory canal is drilled away after reflecting dura off the posterior temporal bone. **D:** The tumor is sequentially debulked and removed. SS, sigmoid sinus; TC, transverse crest; C, cochlear nerve; LA, labyrinthine artery; AICA, anterior inferior cerebellar artery; VII, facial nerve; IX, glossopharyngeal nerve; X, vagal nerve; XI, spinal accessory nerve; JB, jugular bulb; SCA, superior cerebellar artery; PICA, posterior inferior cerebellar artery; SVN, superior vestibular nerve; REZ, root entry zone. *(Continued on next page)*

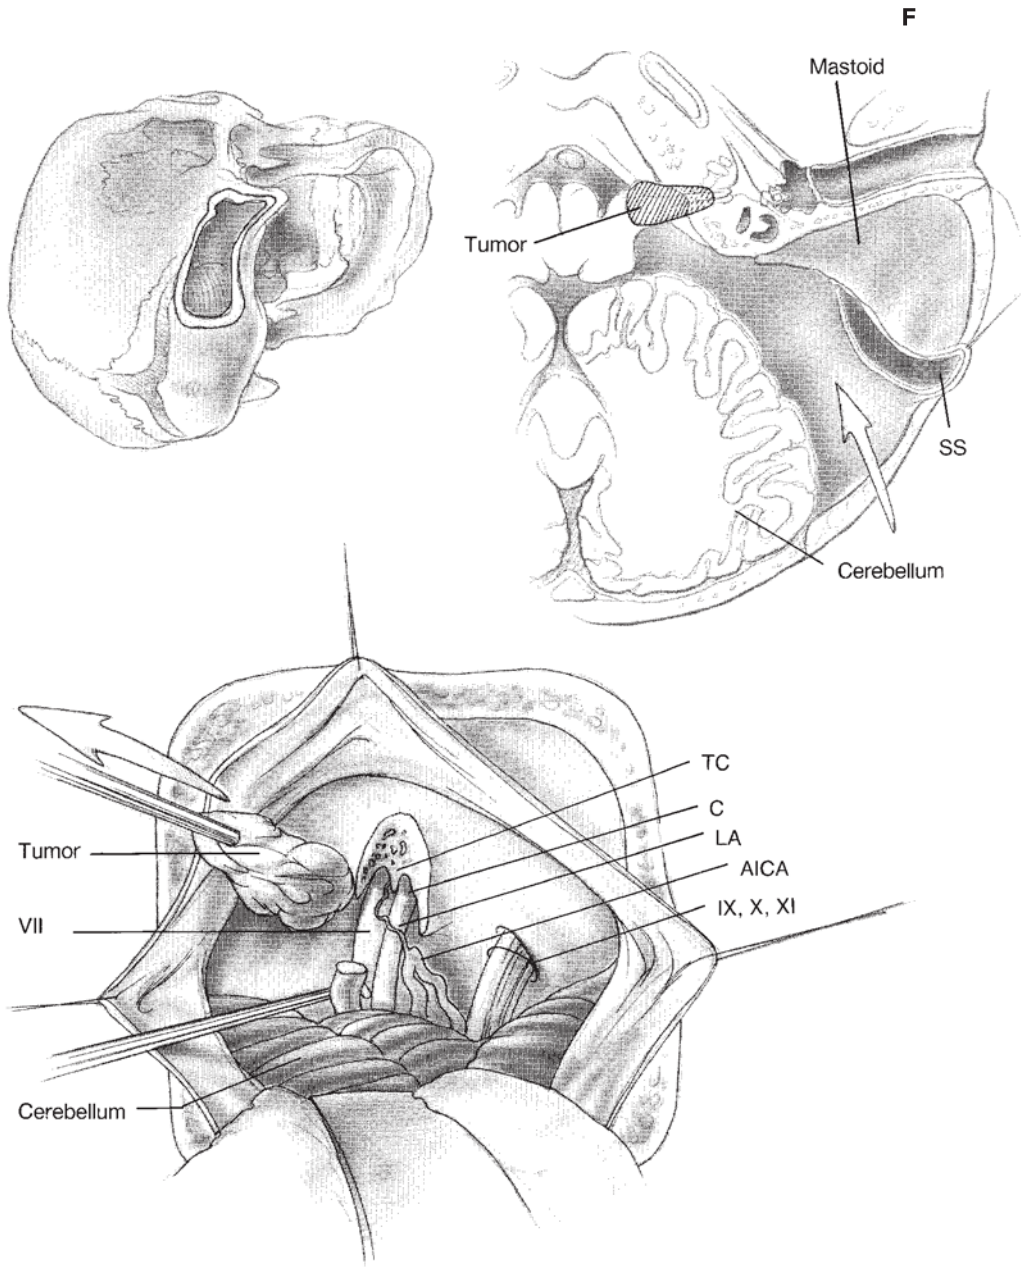

Figure 159.11 *(Continued)*

Approximately 2 to 4 cm from the postauricular crease, a C-shaped incision is performed. Dissection is performed through the dermis and the subcutaneous space is developed. Temporalis fascia and muscle are harvested and placed on the back table. A T-shaped incision is then performed through the musculoperiosteum at the linea temporalis and along the mastoid cortex. The periosteum is widely elevated to expose the mastoid. A complete mastoidectomy is carried out with wide exposure of the middle and posterior fossa dura and at least 1 cm extension posterior to the sigmoid sinus. The facial nerve is identified by removing the bone overlying the nerve at its second genu in the facial recess and the distal course of the vertical portion of the facial nerve is identified. The surgical buttress and facial recess air cells are removed and the incus is removed to facilitate visualization of the eustachian tube orifice. The dural bony plates overlying the middle and posterior fossa are removed along with the bone overlying the sigmoid sinus. Prior to opening the otic capsule, the patient's imaging studies and audiogram are checked again to confirm the correct patient and surgical site. The labyrinthectomy is performed at this point by widely opening the semicircular canals and then extending the bony dissection inferiorly through the retrofacial air cells. The jugular bulb, which is the inferior extent of the dissection, is defined and bony dissection continues through the petrous bone to

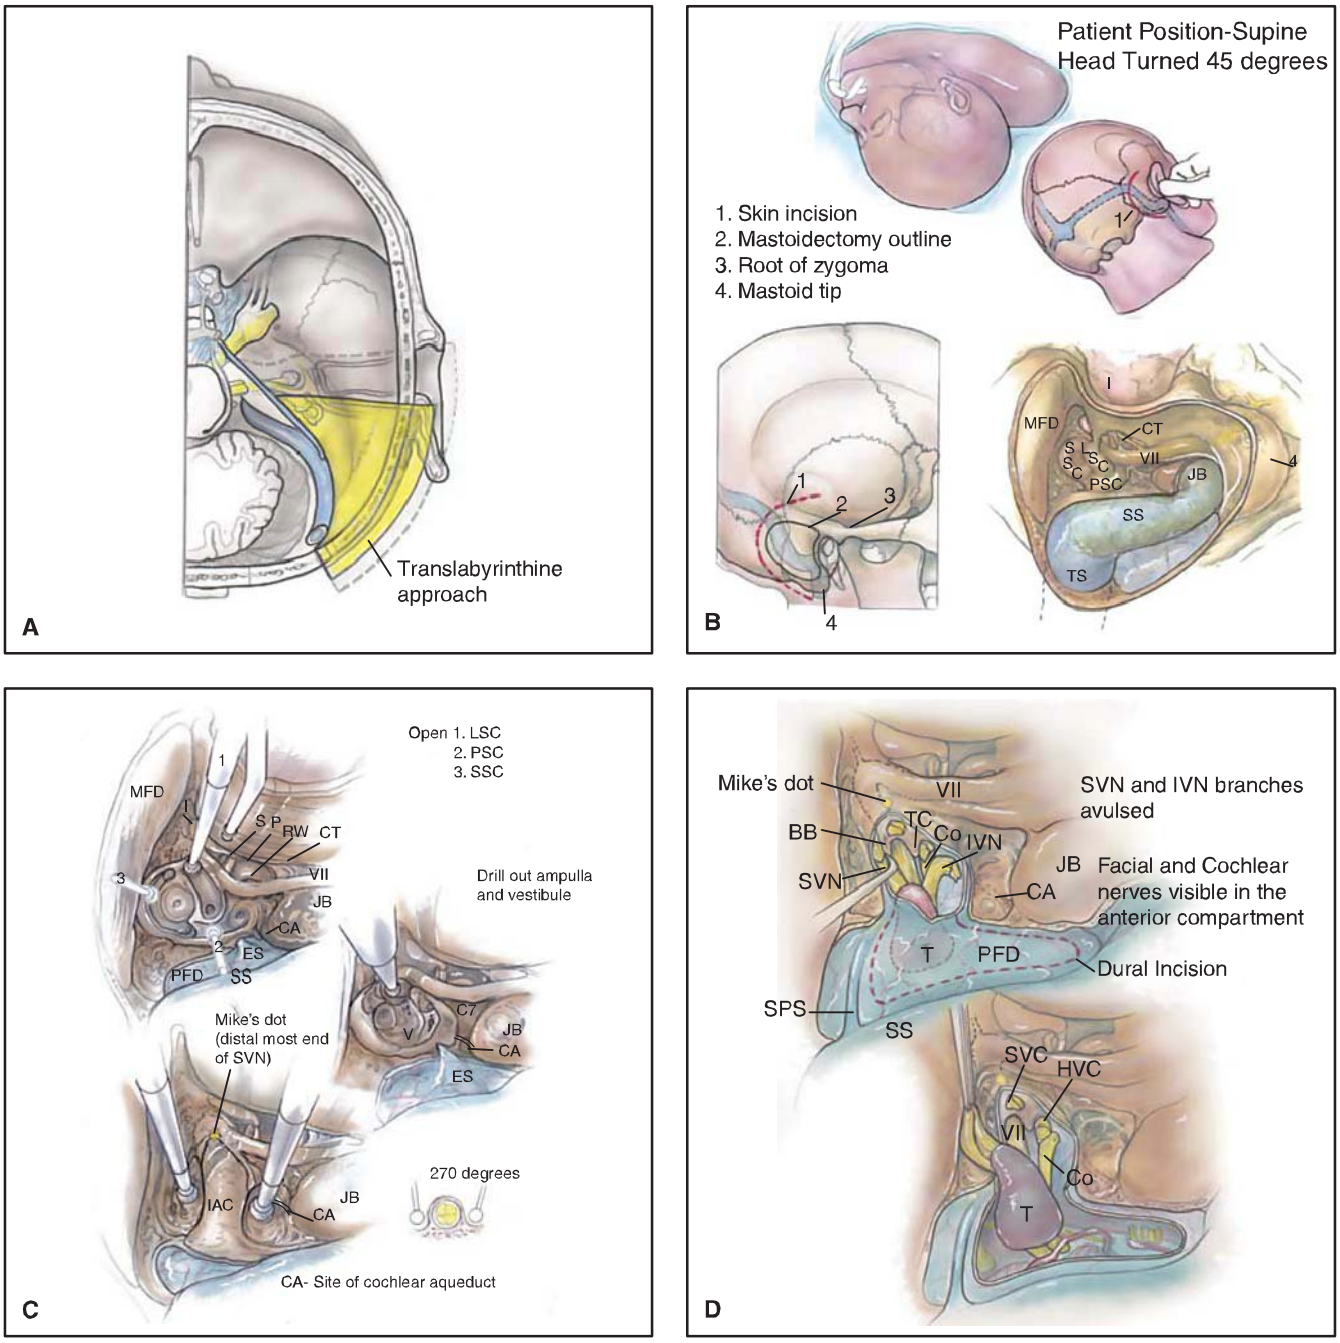

Figure 159.12 Translabyrinthine tumor removal. **A:** The tumor removal is accomplished between the posterior external auditory canal and internal auditory canal anteriorly and the sigmoid sinus posteriorly avoiding prolonged cerebellar retraction. **B:** Patient positioning and skin incision is shown with the complete mastoidectomy then carried out. **C:** Labyrinthectomy with identification of the internal auditory canal and skeletonization. **D:** Dural incision of the internal auditory canal and posterior fossa. Figure 159.12 *(Continued)*

identify the IAC. The medial portion of the cochlear aqueduct is identified medial to the jugular bulb and may be opened widely to drain CSF and decompress the dura once all bone drilling is complete. Removal of bone overlying the lateral IAC will reveal the transverse crest. The macula cribrosa superioris (Mike's dot) is the landmark for the lateralmost extent of the IAC and represents the insertion of the superior vestibular nerve into the labyrinth.

When 270-degree exposure around the IAC has been obtained, the posterior fossa dura is opened widely medial to the sigmoid sinus and over the posterior face of the IAC. Collagen or gelatin foam is then placed on the cerebellum to prevent desiccation. Arachnoid bands are sharply divided, and CSF is drained from the CPA to allow cerebellar relaxation. The posterior face of the tumor is examined and stimulated to ensure that the facial nerve is not aberrantly displaced posteriorly. The capsule of the tumor is cauterized and a window is removed. The central contents of the tumor are removed to facilitate circumferential extracapsular dissection. Once the tumor

has been debulked internally, dissection along the capsule is performed to gently separate the tumor from the cerebellum and brainstem while cauterizing only the vessels that are intimately attached to the capsule. Care should be taken to not dissect blindly around the tumor as such a maneuver could injure the facial nerve on the anterior surface of the tumor. Generally, the medial facial nerve can be identified at the brainstem with the assistance of the facial nerve monitor stimulator; however, following the facial nerve from the lateral end of the IAC continuously to the brainstem may be preferable as noted hereafter.

Once the tumor has been adequately debulked, the fundus of the IAC is examined. The superior and inferior vestibular nerves are avulsed and gently elevated posteriorly. The position of the facial nerve is identified with the facial nerve stimulator and adhesions between the nerve and the tumor should be sharply divided. The cochlear nerve can be preserved in its native position in the setting of NF2 where cochlear implantation may be attempted; however, the cochlear nerve is generally avulsed from the fundus and removed with the tumor as it is dissected medially. The dissection between the tumor and the facial nerve continues to the CPA. Once the tumor is free from the facial nerve, the root entry zone of the eighth cranial nerve is identified, cauterized, and sharply divided. At this point the tumor can be removed from the wound.

The closure of the translabyrinthine wound is performed meticulously to prevent postoperative CSF leak. The petrous bone adjacent to the IAC should be obliterated with bone wax. The middle ear is examined and the tensor tympani tendon is divided to allow visualization and access to the eustachian tube orifice, which is packed with muscle, bone wax, or other packing material. The middle ear is filled with pieces of temporalis muscle, and temporalis fascia is placed over the aditus ad antrum and the undersurface of the labyrinth, which is adjacent to the sinus tympani. Approximately 30 to 50 mL of abdominal fat is harvested and cut into strips. The strips are gently placed into the wound to fill the durotomy and close off the CSF egress. The remainder of the mastoid cavity is filled with the fat, and placement of a titanium mesh plate over the defect fixed with titanium screws holds the fat securely in place and prevents postoperative deformity. The periosteum and skin are closed in multiple layers in a watertight fashion and a pressure dressing is applied.

Combined Approach

The combined approach involves both translabyrinthine and suboccipital approaches as previously described and can be used to resect tumors larger than 4 cm. The procedure is complicated by prolonged operative time and involves collaboration among the surgical team. Postoperative management may include evaluation and treatment of elevated intracranial pressure and hydrocephalus. Neurosurgical consultation is beneficial. Preoperative high-dose steroid administration may help reduce edema if present. Proceeding directly to surgery with opening of the posterior fossa could lead to catastrophic brain herniation and death if the edema is not managed initially.

Surgical Results

Historically, surgery for tumors of the CPA involved high rates of mortality; however, this has dramatically dropped over the past century of cranial base surgery. The mortality rate for surgical excision of vestibular schwannoma has declined to less than 1% (142,143). Postoperative patients should be monitored initially in an ICU setting since emergencies do occur and must be dealt with promptly (Table 159.1). Recurrence of tumor is variable but is generally reported at less than 1% (144,145). Postoperative facial nerve function is dependent on the size of the tumor, the adherence to the facial nerve and the experience of the operating team (146). The translabyrinthine approach can preserve facial nerve function (House Brackmann grade I or II) in over 90% of patients with tumors less than 1.5 cm; however, this rate decreases as tumor size increases (145). The intraoperative facial nerve monitor findings can positively predict postoperative facial nerve function. A House-Brackmann grade I or II postoperative facial nerve outcome can be predicted with 98% probability when the facial nerve response is 240 mV or greater with a 0.05 mA or less stimulus (147). Hearing preservation also varies greatly and depends on the surgical approach and the size of the tumor. In small tumors, hearing can be preserved in 80% to 90% of cases with a middle cranial fossa approach. Postoperative CSF leak remains as one of the more common postoperative complications and the incidence has been reported from 1% to 10% of cases (148–150). Meningitis represents a serious concern in the postoperative period; the rate is reported between 1% and 8% of cases (151). Headache may be a primary preoperative symptom for up to 60% of vestibular schwannoma patients (152). Postoperative headaches are more common in patients who undergo a suboccipital tumor resection

TABLE 159.1 EMERGENCIES AFTER TUMOR REMOVAL

Emergency	Management
Intracranial hemorrhage	Remove dressing and open wound, to allow rapid decompression of brainstem; move to operating room for control of hemorrhage.
Pneumocephalus	If unstable, emergency craniotomy to remove air; otherwise, discontinue lumbar drain and observe.
Meningitis	Lumbar puncture for culture and sensitivity; appropriate antibiotics intravenously; surgical closure of any CSF leak.
CSF leak	Pressure dressing; if leak persists despite lumbar drain, surgical closure.

and may be present in over 30% of patients (153). The etiology of the headache is unknown, but may be related to dural tension and persistent inflammation following closure. The majority of these patients experience resolution of their headaches over time.

NONVESTIBULAR CRANIAL NERVE SCHWANNOMAS

Schwannomas can develop on the fifth through the twelfth cranial nerves within the posterior fossa; however, they are far less common than vestibular schwannomas. Though they tend to have similar imaging characteristics to vestibular schwannomas they differ in their anatomic locations and associated symptoms. As these tumors expand within the CPA they may present similarly. Nonvestibular schwannomas account for 2% to 3% of tumors within the CPA (154) and are common in NF2 patients. Trigeminal schwannoma is the most common of nonvestibular schwannomas (12) and may involve the nerve root or the ganglion. These tumors tend to present with ipsilateral facial hypesthesia in the distribution of the trigeminal nerve. CT imaging demonstrates an enhancing expansion of the Meckel cave or the foramen lacerum. MRI imaging reveals an enhancing lesion in an anterior–posterior orientation adjacent to the Meckel cave that may be difficult to distinguish from a meningioma. Lesions extending into the Meckel cave can be treated with radiation or they can be resected through the anterolateral intradural approach (Dolenec's) and anterior petrosal approach (155).

Facial schwannomas may be difficult to distinguish from vestibular schwannomas if they are limited to the IAC. Multiple segments of the nerve may be involved, and the CPA is involved in greater than 50% of tumors (154). These slow-growing tumors present with gradual facial nerve weakness. Imaging reveals expansion of the fallopian canal within the temporal bone on CT imaging. MRI imaging may reveal an enhancing dumbbell-shaped expansion of the intratemporal facial nerve as well as enlargement and enhancement of the middle fossa geniculate ganglion region (Fig. 159.13). Patients with House-Brackmann facial nerve function I to III are managed initially with observation. Declining facial nerve function may be treated surgically with decompression of the facial nerve via a middle fossa approach or transmastoid approach depending on the location of tumor expansion. When the facial nerve becomes nonfunctional (House-Brackmann IV to VI) resection of the schwannoma may be selected followed by a greater auricular or sural nerve cable graft.

Lower cranial nerve schwannomas typically involve the inferior aspect of the posterior fossa; however, they can extend into the CPA and account for 1% of CPA lesions (154). The clinical symptoms are related to the nerve of origin but expansion of the tumor may affect all of the lower cranial nerves. MRI and CT imaging may reveal an enhancing lesion of the CPA, but typically includes expansion of the jugular foramen (Fig. 159.14). Treatment of these lesions may involve surgical resection or radiation.

Figure 159.13 Axial T1-weighted contrast-enhanced MRI image at the level of the IAC demonstrating a right facial schwannoma. Note the enhancing mass (*arrowhead*) in the lateral IAC along with enhancement along the labyrinthine segment (*arrow*) of the facial nerve and the geniculate ganglion.

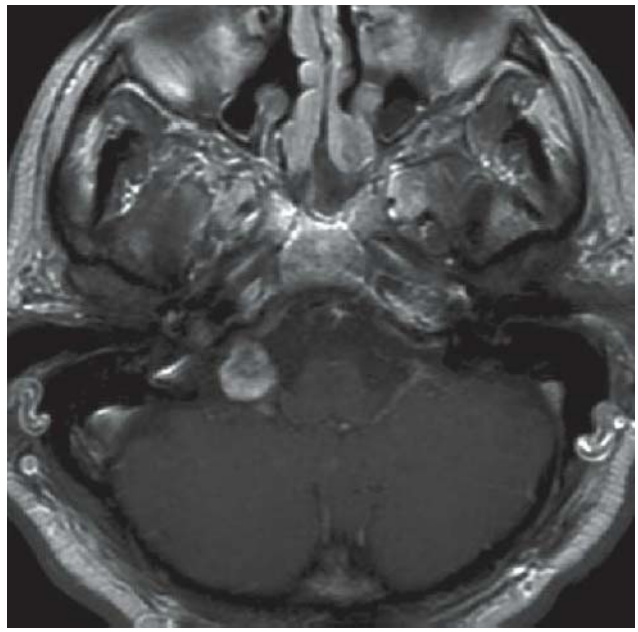

Figure 159.14 Axial T1-weighted contrast-enhanced MRI image at the level of the jugular foramen demonstrating a right glossopharyngeal nerve schwannoma. Note the enhancing mass extending from the pars nervosa of the jugular foramen into the lateral medullary cistern.

MENINGIOMA

Epidemiology

Meningiomas are the most common intracranial extraaxial tumor and account for approximately 20% of all primary intracranial tumors. The majority of these tumors occur along the convexity of the cranial vault; however, they are the second most common neoplasm of the CPA and can lead to significant morbidity when they occur along the cranial base. These tumors comprise 10% to 15% of all CPA tumors (156) and develop from the arachnoid villi cap cells adjacent to dural sinuses and may have broad dural attachments. Meningiomas are more common in middle-aged women. Sex hormone receptors and metabolism may play a role in development and progression of these tumors (154).

Histopathology

The World Health Organization has classified meningiomas as grade I (benign) (80%), while 10% to 15% are grade II or atypical, and 2% to 5% are malignant or grade III (157). Multiple histologic subtypes have been described and grade I variants include meningothelial, fibrous, transitional, psammomatous, angiomatous, microcystic, secretory, lymphoplasmacyte-rich, and metaplastic (158). Classically, grade I tumors display whorls of spindle cells with the presence of calcified psammoma bodies. Grade II tumor variants display increased cellularity, atypical nuclei, and areas of necrosis (159). Grade III tumors are anaplastic and may have papillary or rhabdoid variants and display high proliferation indices with brain invasion (158). Immunohistochemical staining is helpful in the diagnosis of meningiomas and common markers for these tumors include epithelial membrane antigen and vimentin (158). Additionally, an anti-phosphohistone H3 can help identify mitotically active areas within tumors (160).

Sporadic meningiomas are common; however, NF2 patients may develop multiple meningiomas that often lead to increased morbidity and mortality. Whether associated with NF2 or not, these benign tumor types occur along the skull base and can invade the dura, dural sinuses, skull, orbit, soft tissue, and skin. Although they may be displaced by the tumor, cranial nerves are frequently enveloped by meningiomas, thus, complicating attempts at neurologic preservation. The broad dural base and infiltrative nature of these tumors make them difficult to completely resect and recurrences are common.

Molecular Biology

Meningiomas commonly have chromosomal deletion, and may involve multiple chromosomal anomalies in grade II and III tumors (161). Mutations resulting in deletion or inactivation of the *NF2* gene are common and occur in 30% to 70% of sporadic meningiomas (162). Additional genes are likely involved as well, such as NF1, PTCH, CREBBP, VHL, PTEN, and CDKN2A (reviewed in 163), and meningiomas have been associated with hereditary syndromes, including Cowden, Gorlin, Li-Fraumeni, Turcot, Gardener, von Hippel-Lindau, and multiple endocrine neoplasia type I (158). Meningioma development and progression has been linked to altered intracellular signaling involving p53, retinoblastoma protein interactions, and tyrosine kinase receptors such as epidermal growth factor receptor and platelet derived growth factor receptor (164–166).

Clinical Presentation

Meningiomas of the cranial base and CPA present with symptoms dependent upon their size and location. Tumors that originate along the floor of the middle cranial fossa can induce facial and/or ocular pain and diplopia from dysfunction of the trigeminal and trochlear nerves. Expansion of the tumor to compress the temporal lobe can result in seizures and sensory/motor deficits. Tumors that extend more anteriorly along the petroclival region may involve the abducens nerve, which can also result in ocular symptoms. When these lesions involve the CPA and IAC, the symptoms mirror vestibular schwannomas and may make it difficult to distinguish these tumors.

It is difficult to distinguish between vestibular schwannomas and meningiomas by audiovestibular testing. Imaging can often differentiate the two tumors. Extension of these tumors inferiorly may result in dysfunction of the lower cranial nerves with resulting dysphagia, dysphonia, shoulder weakness, and tongue hemiparalysis. Similar to vestibular schwannomas, meningioma growth within the CPA can compress the brainstem and produce hydrocephalus and, potentially, lethal brain herniation.

Diagnostic Evaluation

Audiologic and vestibular tests may reveal dysfunction of the vestibulocochlear nerve caused by meningiomas and may be indistinguishable from the dysfunction caused by vestibular schwannomas. Imaging studies are vital in the diagnosis of meningiomas. CT imaging of meningiomas may identify calcified areas and contrast enhancement of these tumors is heterogeneous. The bone adjacent to meningiomas may also be altered and have hyperostotic changes. Meningiomas appear isointense or slightly hypointense to gray matter on T1-weighted MRI sequences, with variable intensity on T2-weighted images and they display enhancement with gadolinium on T1-weighted images. The configuration of meningiomas is useful in the differential diagnosis since these tumors usually have a broad base of dural enhancement and form an obtuse angle with the underlying bone. There may also be extension of enhancement along the underlying

Figure 159.15 Axial T1-weighted contrast-enhanced MRI image at the level of the IAC demonstrating a right CPA meningioma with broad dural attachment and enhancement.

dural surface, which is known as a dural tail (Fig. 159.15). Meningiomas may occur adjacent to or in the IAC-like vestibular schwannomas. Tumor progression may result in erosion of bone of the cranial base and invasion of tumor into neural foramina or into the middle ear.

Treatment Options

The management of cranial base meningiomas is complex and may employ multiple modalities to preserve neurologic function and tumor control. The complex anatomy of the cranial base complicates the intervention for these tumors. The risks and benefits of each treatment option must be analyzed in terms of the surrounding structures and the natural history of the meningiomas. Although these tumors are typically benign and slow growing, they can be aggressive and resilient to eradication. The primary treatment options are the same as vestibular schwannomas and include observation, radiation therapy, and microsurgical resection.

Observation with serial imaging studies and audiometry remains a viable option for patients, especially in those of advanced age or unable to undergo surgery. The natural history of meningioma growth over an extended period of observation with serial imaging demonstrated 27% of patients with declining cranial nerve function. At 10-year follow-up, only 42% had no tumor progression. Forty percent of patients within this study eventually underwent some form of treatment (167).

Radiation therapy for meningiomas can be administered in the form of gamma photons through stereotactic radiosurgery, x-ray photons in fractionated radiotherapy, and proton beam therapy. Focused radiation techniques have gained popularity to concentrate discrete radiation doses to the tumor and minimize exposure of normal surrounding structures. Radiation can be utilized as a primary treatment or as an adjuvant modality for meningiomas and is indicated in patients in whom surgery is not desired, is not deemed safe, or is unlikely to accomplish complete resection without significant morbidity. When meningiomas impinge on sensitive neurovascular structures, debulking may relieve compression and may decrease radiation treatment complications. Additionally, radiation therapy following tumor debulking can be used to improve tumor control (168). Tumor control of 82% to 100% for cranial base meningiomas after stereotactic radiation with doses from 12 to 17 Gy has been reported. The same studies noted progressive neurologic decline from 0% to 27% (169–173).

Considering the aggressive nature of meningiomas, microsurgical resection is considered the gold standard of treatment when growth or progressive symptoms are noted. Complete resection is not always feasible but decompression of surrounding neurovascular structures may provide symptomatic relief and provide tissue for histopathologic diagnosis. The approach for microsurgical resection of meningiomas is based on the anatomic areas involved as well as the hearing status. Meningiomas isolated to the CPA with preserved hearing may be approached, as would a vestibular schwannoma. Considering the dural involvement of these tumors, it is advisable to widely excise surrounding dura to prevent recurrence. Patients with meningiomas who lack functional hearing are best managed with a translabyrinthine approach. The variable location of the facial nerve in CPA meningiomas makes the translabyrinthine approach, with its extensive facial nerve exposure, a desirable route for resection. The middle fossa approach is not commonly used to resect meningiomas; however, lesions isolated to the IAC with functional hearing can be approached in this manner. Meningiomas frequently extend anteriorly into the petroclival region that can be accessed through a transcochlear approach. This approach involves a translabyrinthine dissection followed by posterior translocation of the facial nerve from the fallopian canal. Drilling continues, in an anteromedial direction, through the cochlea using caution so as to not injure the intratemporal segment of the carotid artery. This approach provides ample exposure of the clivus and the Meckel cave; however, translocation of the facial nerve can result in its dysfunction. This region can also be approached via a transpetrosal middle fossa approach by removing intervening bone between the cochlear and internal carotid artery. The risk associated with microsurgery for meningiomas is similar to that of vestibular schwannomas and are inherent to the

approach being utilized. Resection of tumors in the CPA and petroclival region can greatly reduce the risk of neurovascular compromise and facilitate adjuvant therapy; however, recurrence and iatrogenic neurologic deficit remain concerns. In a review of 150 patients with anterior CPA and petroclival meningiomas treated with microsurgery, 20% developed new neurologic deficits. Gross total resection was accomplished in 32% of patients, subtotal resection in 43% and partial resection in 25%. The mean follow up was 102 months. This review also analyzed the literature and reported total resection rates of 40% to 79% and recurrence or progression rates as 0% to 36% (174).

EPIDERMOID AND DERMOID CYSTS

Epidermoid cysts are congenital lesions that develop from sequestered ectodermal epithelial cell rests. They are synonymous with cholesteatoma; however, acquired cholesteatomas can also occur within the CPA from extension from the mastoid, middle ear, or petrous bone. This collection of squamous epithelial cells grows slowly by desquamation of cells and accumulation of keratin debris. Similar to middle ear cholesteatomas, they tend to erode surrounding bone and encase neurovascular structures. Epidermoids represent the third most common mass of the CPA, comprising approximately 5% of all masses in the region (175). Dermoid cysts develop from inclusion of cutaneous ectoderm, like epidermoids; however, these lesions differ, in that, they include fat and adnexal components. Dermoid cysts are uncommon lesions of the CPA and more commonly originate from the parasellar region (176) and contain fat, hair, calcifications, keratin debris, and products of sebaceous glands (13).

Clinically, these lesions experience extensive occult growth without causing dramatic symptoms until they are considerable in size. Symptoms are similar to other discrete tumors of the CPA; however, they may cause earlier facial neuropathy compared with lesions that only displace the nerve. CT imaging reveals remodeling of bone surrounding these lesions (Fig. 159.16A), and may identify calcifications in dermoid cysts. MRI is helpful in the diagnosis and displays epidermoid cysts as irregular nonenhancing lesions that are hypointense on T1-weighted images and hyperintense on T2-weighted images (Fig. 159.16B and C). The use of fluid-attenuated inversion recovery (FLAIR) sequences is helpful in the diagnosis, which suppresses of the signal intensity of CSF, and epidermoid cysts appear as hyperintense lesions. Additionally, diffusion-weighted imaging, which monitors the diffusion of fluid-filled structures or spaces, displays epidermoid cysts as hyperintense lesions, unlike arachnoid cysts (Fig. 159.16D). Dermoid cysts have similar characteristics and are also nonenhancing; however, they display intrinsic high T1 signal intensity due to the fatty dermal component.

The primary treatment of these lesions is microsurgical excision through one of the approaches already described. Similar to this disease process in the middle ear and mastoid, recurrences are common; thus, great care must be taken to remove all disease. The central contents of these cysts can easily be debulked with suction and blunt dissection to facilitate circumferential dissection and resection of the capsule. Cysts that envelop vital neurovascular structures can be managed with subtotal resection and monitored with imaging since these are slowing growing lesions. One recent review reported recurrence rates of 23% for epidermoid cyst total resection and 27% for subtotal resections and the majority of recurrences required surgical intervention (177).

ARACHNOID CYST

Arachnoid cysts are congenital malformation of the arachnoid that result in a pouch of sequestered normal CSF fluid. The etiology of cyst formation is unknown. These lesions comprise less than 1% of intracranial lesions and approximately 10% occur in the CPA, while most occur in the supratentorial temporal fossa (154). These lesions are typically asymptomatic but can cause compression of the seventh and eighth cranial nerve complex. MRI characteristics of arachnoids cysts are a nonenhancing lesion that is hypointense on T1-weighted images and hyperintense on T2-weighted images. These cysts displace neurovascular structures and have smooth regular borders that do no invade or envelope vital structures. Arachnoid cysts appear as a hypointense lesion on MRI FLAIR and diffusion weighted sequences. These lesions do not generally require intervention; however, they may be fenestrated via a suboccipital approach to decompress an expanding cyst (154).

LIPOMA

Lipomas of the CPA are uncommon and are due to congenital malformations resulting in hamartomatous collections of mature adipose tissue. These lesions more commonly occur in supratentorial locations and can be associated with cerebral malformations; however, lipomas of the CPA are not associated with other defects (175). These lesions tend to envelop neurovascular structures and may adhere tightly to cranial nerves. These lesions tend to grow very slowly over time but may induce similar symptoms to other CPA masses, such as facial paralysis, hearing loss, and trigeminal neuralgia. Lipomas appear as nonenhancing lesions that are hyperintense on T1-weighted images and hypointense on fat-suppressed T2-weighted images (Fig. 159.17). The diagnosis can be confirmed by performing fat suppression on unenhanced T1 sequences, which causes lipomas to appear hypointense. These lesions are typically managed with serial imaging; however, they may be treated with subtotal resection in the event of neurovascular compression.

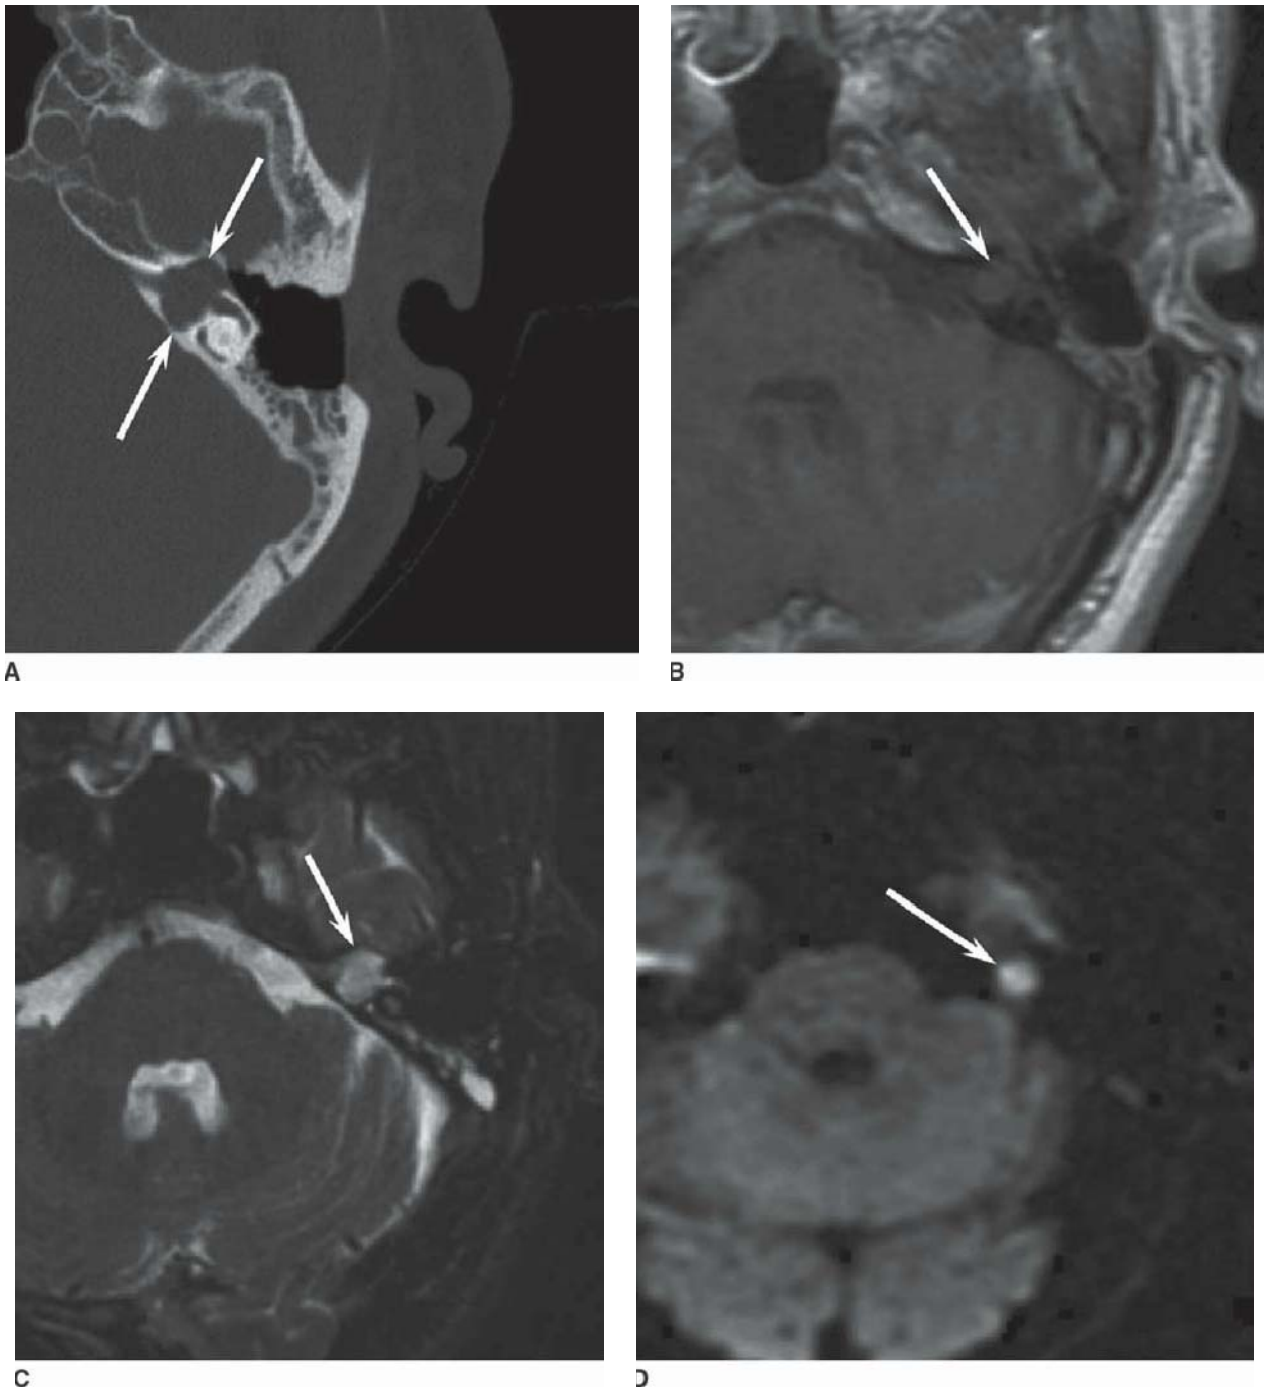

Figure 159.16 Radiographic appearance of recurrent acquired cholesteatoma. Axial CT of the temporal bone demonstrating a mastoidectomy defect with a smooth expansile mass (*arrows*) eroding the inner ear **(A)**. This mass is isointense to brain and nonenhancing on axial T1-weighted contrast-enhanced MRI image **(B)**, but hyperintense on T2-weighted images **(C)** and diffusion-weighted images **(D)**. The restricted diffusion distinguishes recurrent cholesteatoma from scar.

MISCELLANEOUS EXTRAAXIAL LESIONS

Metastases

Metastatic lesions to the CPA are uncommon and account for less than 1% of CPA lesions (178). These lesions may present as a discrete mass or as diffuse meningeal disease, also known as leptomeningeal carcinomatosis. The most common primary tumors that CPA metastases originate from are lung, breast, melanoma, and lymphoma (179). Metastases present with acute cranial neuropathies and may cause bilateral symptoms, mimicking NF2. A history of cancer should raise suspicion of metastatic disease. Diagnosis can be made with CSF cytology (180,181). Metastases typically appear as enhancing lesions on T1-weighted images and

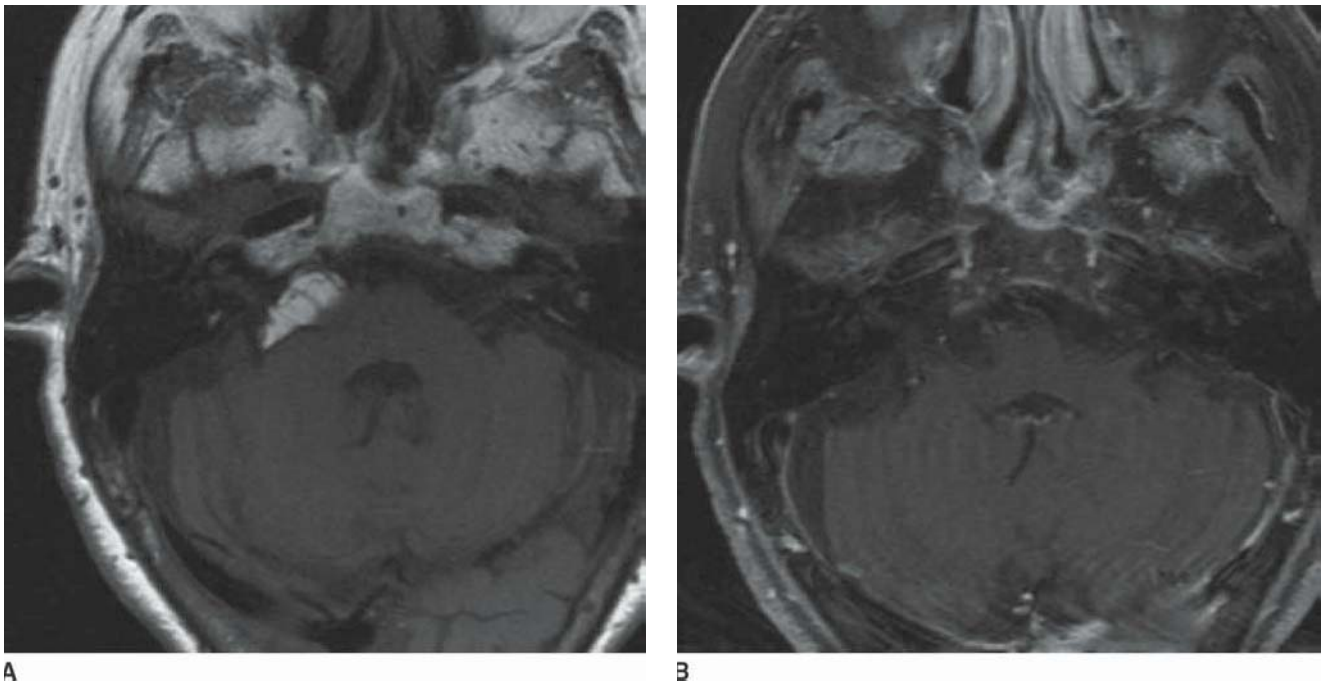

Figure 159.17 Axial T1-weighted unenhanced MRI image at the level of the IAC demonstrating a right CPA lipoma **(A)**. The diagnosis is confirmed with a postcontrast fat-suppressed T1 MRI image as this lesion appears dark **(B)**.

may show irregular bony destruction on CT (Fig. 159.18). Melanoma, due to the paramagnetic activity of melanin, may appear with intrinsic T1 hyperintensity, without contrast (12). A careful systematic search for the primary lesion must be undertaken when the CPA lesion is the first to be diagnosed. Treatment of these lesions is usually dictated by a multidisciplinary team of oncologists and surgeons and often involves multimodality treatment. Surgical intervention is typically reserved for palliation or for the purpose of obtaining tissue for pathologic diagnosis.

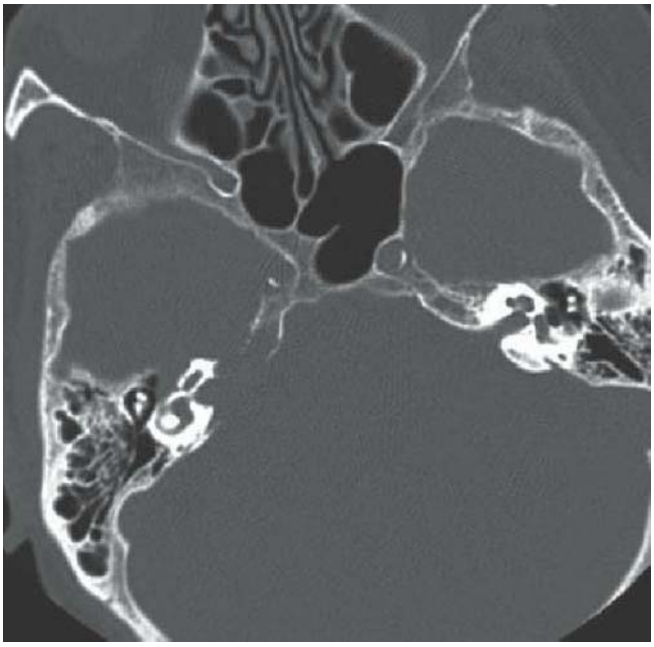

Figure 159.18 Axial bone-window CT shows erosion of the right petrous apex from metastatic renal cell carcinoma.

Vascular Lesions

Lesions of vascular origin account for approximately 3% of CPA and most of those are aneurysms of the vertebral arterial system, such as the AICA (182). The complex vascular system of the CPA can cause compression of the seventh to eighth cranial nerve complex when abnormal vascular loops or aneurysmal dilations develop. Aneurysms may present with subarachnoid hemorrhage and/or cranial neuropathy. These lesions may appear as discrete lesions of the CPA with flow voids and enhance with contrast administration on MRI. These lesions may be asymptomatic and are typically managed with surgical clipping through a suboccipital approach (183) or endovascular occlusion (184). Although a controversial diagnosis, ipsilateral auditory/vestibular symptoms and trigeminal neuralgia have been linked to aberrant vascular loops and can be managed with surgical decompression (185).

Hemangiomas, arteriovenous malformations (AVMs), and cavernomas can also develop with the CPA. Hemangiomas more commonly occur at the geniculate ganglion and develop from vessels that accompany the facial nerve (186). Calcifications within these lesions may be identified on CT and they appear as enhancing lesions with flow voids. An AVM is an abnormal collection of arteries and veins that, unlike other vascular malformations, have major feeding and draining vessels. These malformations may

result in significant hemorrhage if they rupture. These may appear similar to other vascular lesions; however, the gold standard for AVM diagnosis is cerebral angiography. These lesions may be observed if small and asymptomatic; however, they can also be managed with endovascular occlusion, surgical resection, or stereotactic radiosurgery. Cavernomas are abnormal vascular lesions that contain sinusoidal regions of blood products contained by fragile endothelial walls. Unlike AVM, these lesions do not have large feeding or draining vessels. The clinical presentation is similar to other vascular lesions and appears as enhancing heterogeneous lesions with a "popcorn" appearance with a hypointense rim on T1 and T2 sequences. Treatment is typically surgical but is dependent on the size and clinical presentation.

Sarcoidosis

This systemic disease can present with central nervous system (CNS) manifestations. Forty percent of patients with sarcoidosis have leptomeningeal enhancement (175). Granulomas may form within the CPA and may clinically mimic other lesions, although, these lesions may additionally present with signs and symptoms of meningeal inflammation. Due to the diffuse nature of this disease, diagnosis can be difficult; however, these lesions are hyperintense on CT, isointense on MRI T1 sequences, hypointense on T2 sequences, and strongly enhance with contrast administration. Neurosarcoidosis is treated with systemic immune suppression.

Tuberculosis

This disease is known to present with diverse and obscure lesions and CNS tuberculosis can include abscesses, basilar meningitis, and intraaxial tuberculomas. An extraaxial tuberculoma can closely mimic a cranial base meningioma, clinically and radiographically (187). Treatment involves systemic antimycobacterial therapy.

INTRAAXIAL LESIONS

Lesions of the brainstem may present within the CPA. As these lesions expand, normal anatomy is distorted and the fluid-filled CPA is effaced, which can complicate diagnosis. Subtle imaging findings such as an enhancing lesion without a brain–tumor interface and with peritumoral edema are indicative of an intraaxial lesion (13). These lesions are typically managed by or in conjunction with neurosurgery and oncology services.

A wide variety of neoplastic disease can develop in this region. Primary lymphoma may occur as an intraaxial and extraaxial lesion and have the same clinical and imaging characteristics. These lesions can appear hyperintense on CT, which enhance on contrast administration. They appear hypointense on T1 sequences and strongly enhance with gadolinium. These lesions are hypercellular and result in hypointensity on T2-weighted images (13). CNS lymphoma may be the primary presentation of primary immunologic disease. Gliomas present with unilateral expansion of the brainstem with exophytic extension into the CPA; however, the imaging characteristics of glioma are not unique. Hemangioblastomas are benign lesions that are vascular in origin and develop from the cerebellum. Extension into the CPA by hemangioblastoma may mimic vestibular schwannomas (188). Most commonly these lesions are sporadic, but may occur in association with von Hippel-Lindau disease. These encapsulated lesions are strongly enhancing on MRI and may have cystic portions that appear hyperintense on T2-weighted images. Intraventricular lesions, such as ependymoma and papilloma, can extend into the CPA and MRI reveals extension of these tumors from the fourth ventricle through the foramen of Luschka. Similar to the extraaxial presentation, metastatic disease can occur within the brainstem and have similar symptoms and are managed similarly.

SKULL BASE LESIONS

Lesions that develop from or within the temporal bone may extend into the CPA. Bone erosion of the petrous bone can be extensive and CT imaging is particularly helpful in identifying extension and monitoring for recurrence or progression of disease.

Paraganglioma

Glomus tumors of the jugular foramen can extend superiorly into the CPA. These tumors develop from neuroendocrine paraganglial cells originating from neural crest cells adjacent to the ninth and tenth cranial nerves and are surrounded by a dense collection of capillaries and venules. Glomus jugulare tumors are frequently supplied by the ascending pharyngeal artery; however, that may have a variety of additional feeding vessels. Although slowly growing and benign, these lesions can aggressively erode bone and invade neurovascular structures of the cranial base. Pulsatile tinnitus is a hallmark symptom; however, disease that extends into the CPA is likely to have multiple cranial neuropathies. Less than 4% of these tumors secrete vasoactive catecholamines and produce hypertension, palpitations, diaphoresis, and arrhythmias (189). Diagnostic evaluation should involve a 24-hour urine test, if a secreting tumor is suspected, to detect vasoactive tumor products such as vanillylmandelic acid and epinephrine derivatives. CT imaging can identify irregular bony erosion of these tumors (Fig. 159.19). On MRI, these enhancing lesions typically demonstrate a "salt and pepper" pattern, which is due to flow voids within vessels of the tumor (Fig. 159.20). Angiography can also be performed to assist in diagnosis and for embolization. Treatment of glomus tumors is typically surgical; however, lesions that extend into the intracranial compartment may

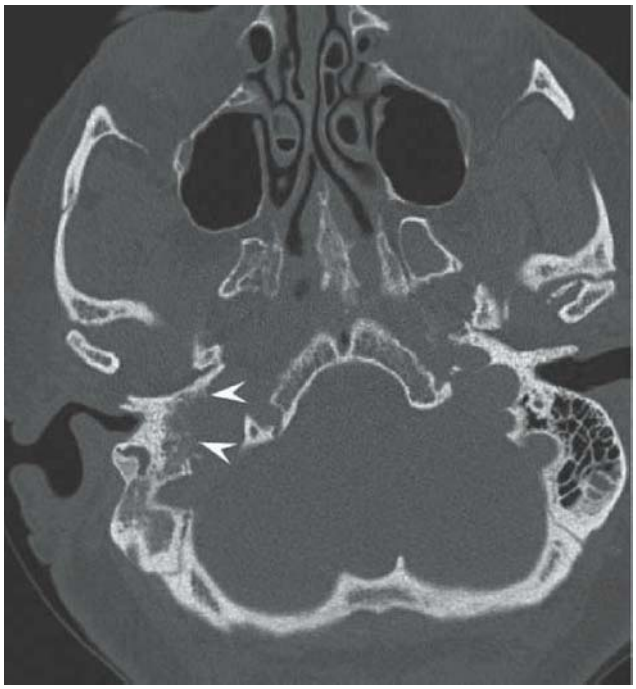

Figure 159.19 Axial temporal bone CT image at the level of the jugular foramen demonstrating permeative bony erosion (*arrowheads*) and loss of the caroticojugular spine caused by a glomus jugulare tumor.

require multiple treatment modalities. Subtotal resection with postoperative adjuvant radiotherapy useful for extensive disease. Surgical resection requires proximal and distal venous control; however, profuse bleeding may occur during resection due to the inferior petrosal sinus.

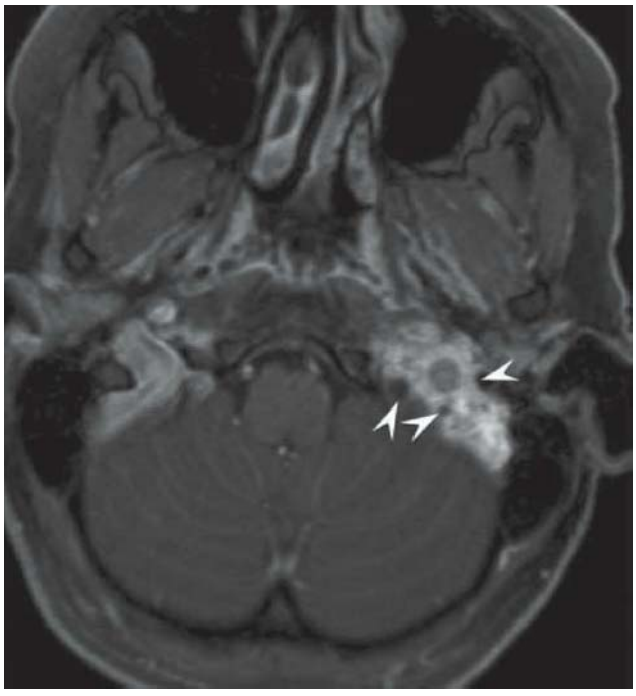

Figure 159.20 Axial T1-weighted contrast-enhanced MRI image at the level of the left jugular foramen demonstrating an enhancing glomus jugulare tumor with dark intratumoral flow voids (*arrowheads*).

Cholesterol Granuloma

Chronic obstruction of air cells of the temporal bone may result in accumulation of secretions and hemorrhage and form cholesterol granulomas. These lesions typically occur in the petrous apex and may slowly expand into the CPA. These lesions may cause similar cranial neuropathy. CT imaging reveals smooth bony expansion of the petrous bone, which may encroach on the petrous carotid artery (Fig. 159.21). The lesions are nonenhancing and appear as hyperintense on T1 sequences and hyperintense on T2 sequences (Fig. 159.22A and B). Observation of these lesions is recommended while asymptomatic; however, drainage of these lesions and their polychromatic "crank case oil" fluid can be performed through a transsphenoidal, middle fossa or infracochlear approach.

Chondromatous Lesions

Cartilaginous components of the petroclival fissure can be the source of chondromas and chondrosarcomas of the cranial base. These lesions originate along the parasagittal petroclival suture and can extend into the CPA. CT imaging can demonstrate calcifications within the tumor as well as the degree of bone erosion. Similar to normal cartilage, chondromatous lesions have poor vascularity and are weakly enhancing. They are hypointense on T1 and hyperintense on T2 images and may have signal voids in areas of calcification (Fig. 159.23A–C). Surgical resection is the primary treatment modality as these lesions are not very radiosensitive.

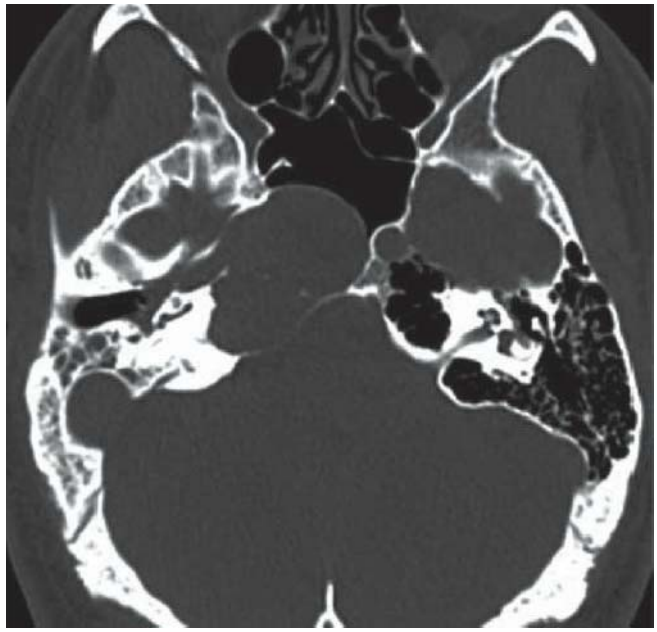

Figure 159.21 Axial temporal bone CT image at the level of the petrous apex demonstrating smooth bony expansion of the right petrous apex caused by a cholesterol granuloma. Note the loss of a distinct border between the lesion and the petrous carotid artery.

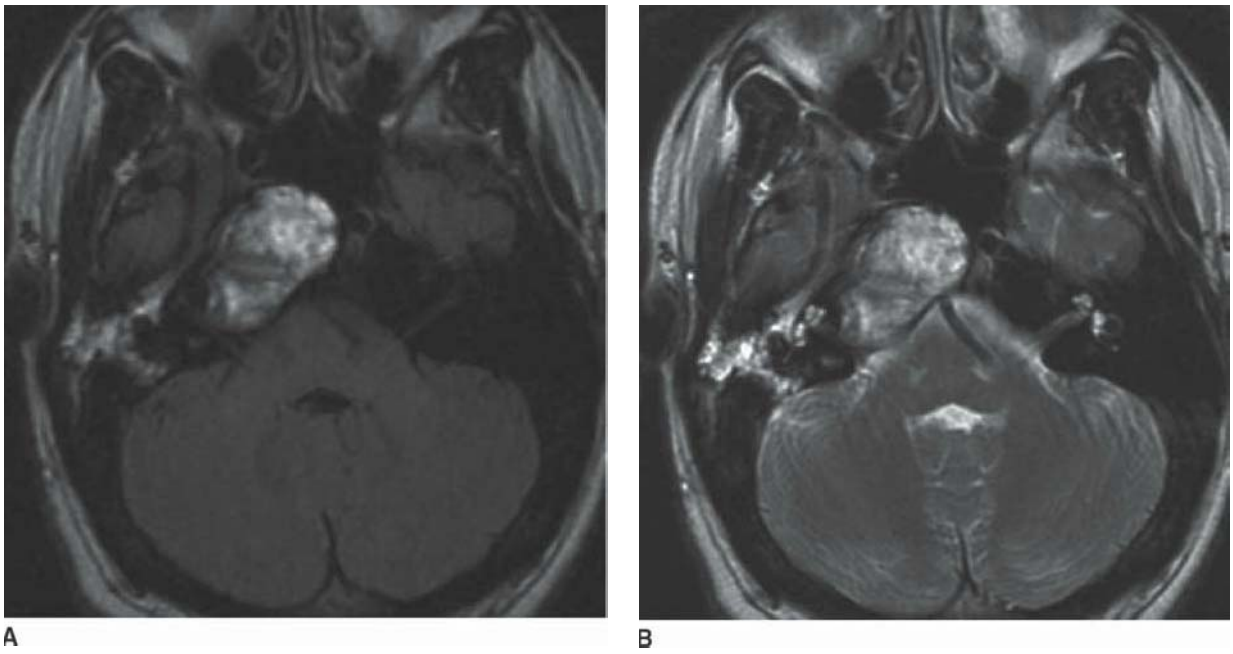

Figure 159.22 Cholesterol granuloma of the right petrous apex is hyperintense on both T1-weighted MRI images **(A)** and T2-weighted images **(B)**.

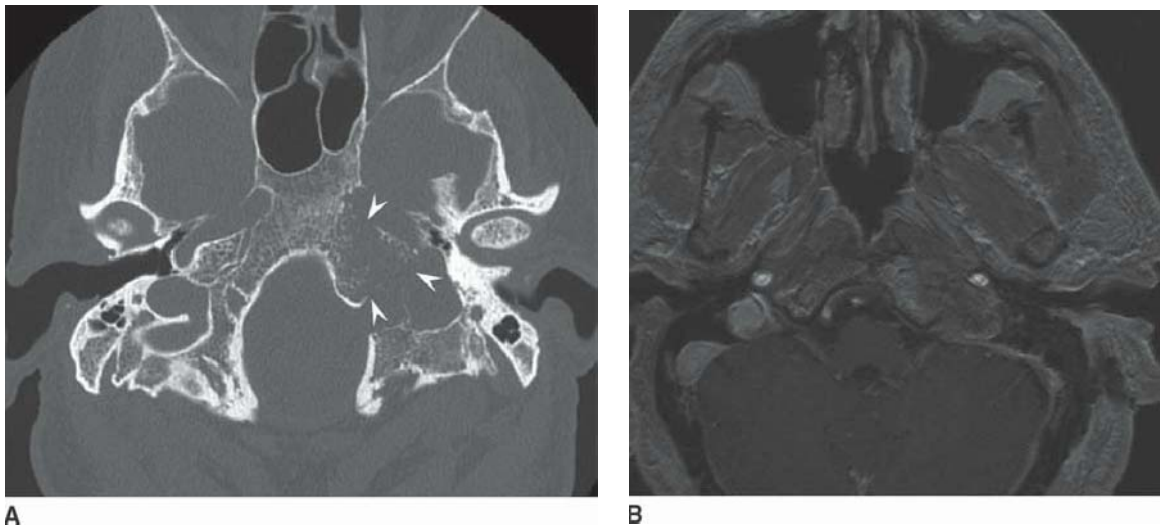

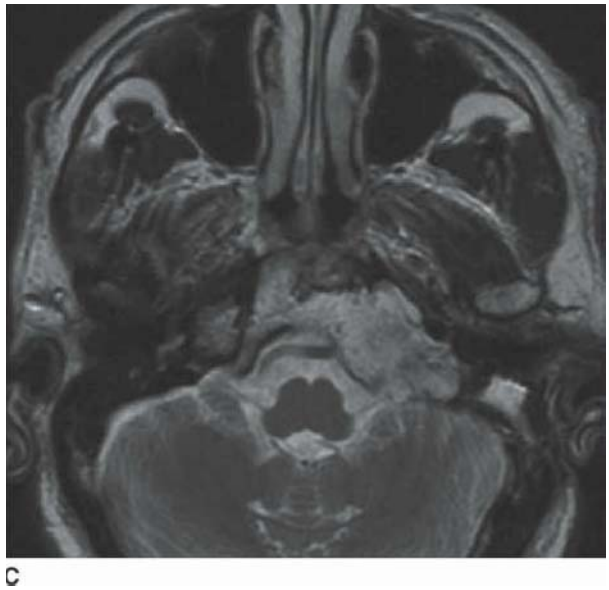

Figure 159.23 Radiographic appearance of a chondrosarcoma. Axial CT **(A)** of the temporal bone at the level of the clivus and jugular foramen demonstrates wide bony destruction (*arrowheads*) of the left cranial base. This mass is mildly enhancing and hypointense on axial T1-weighted contrast-enhanced MRI images **(B)** but hyperintense on T2-weighted images **(C)**.

Chordoma

Chordomas are uncommon slowly growing tumors that develop from clival notochord remnants and seldom extend into the CPA; however, the chondroid chordoma variant may occur within the CPA. These lesions have a distinct histologic appearance that is characterized by the presence of physaliferous or "soap bubble" cells. These lesions appear as well-circumscribed bone-expanding midline lesions on CT and moderately enhancing lesions that appear hypointense on T1 sequences and hyperintense lesions with hypointense septations on T2 sequences (Fig. 159.24A–C). Prognosis of these lesions is poor and treatment involves surgical resection with postoperative radiotherapy.

Endolymphatic Sac Tumors

Tumors that originate from the endolymphatic sac are aggressive lesions that are papillary adenomas originating on the posterior petrous bone and may extend into the CPA. These lesions may occur sporadically but have an association with von Hippel-Lindau disease. Extensive bone erosion of the petrous bone can be identified on CT. These enhancing heterogenous masses can sequester hemorrhagic and protein-laden cysts that may be bright on T1 and T2 sequences. Treatment is surgical through a translabyrinthine approach and postoperative radiation.

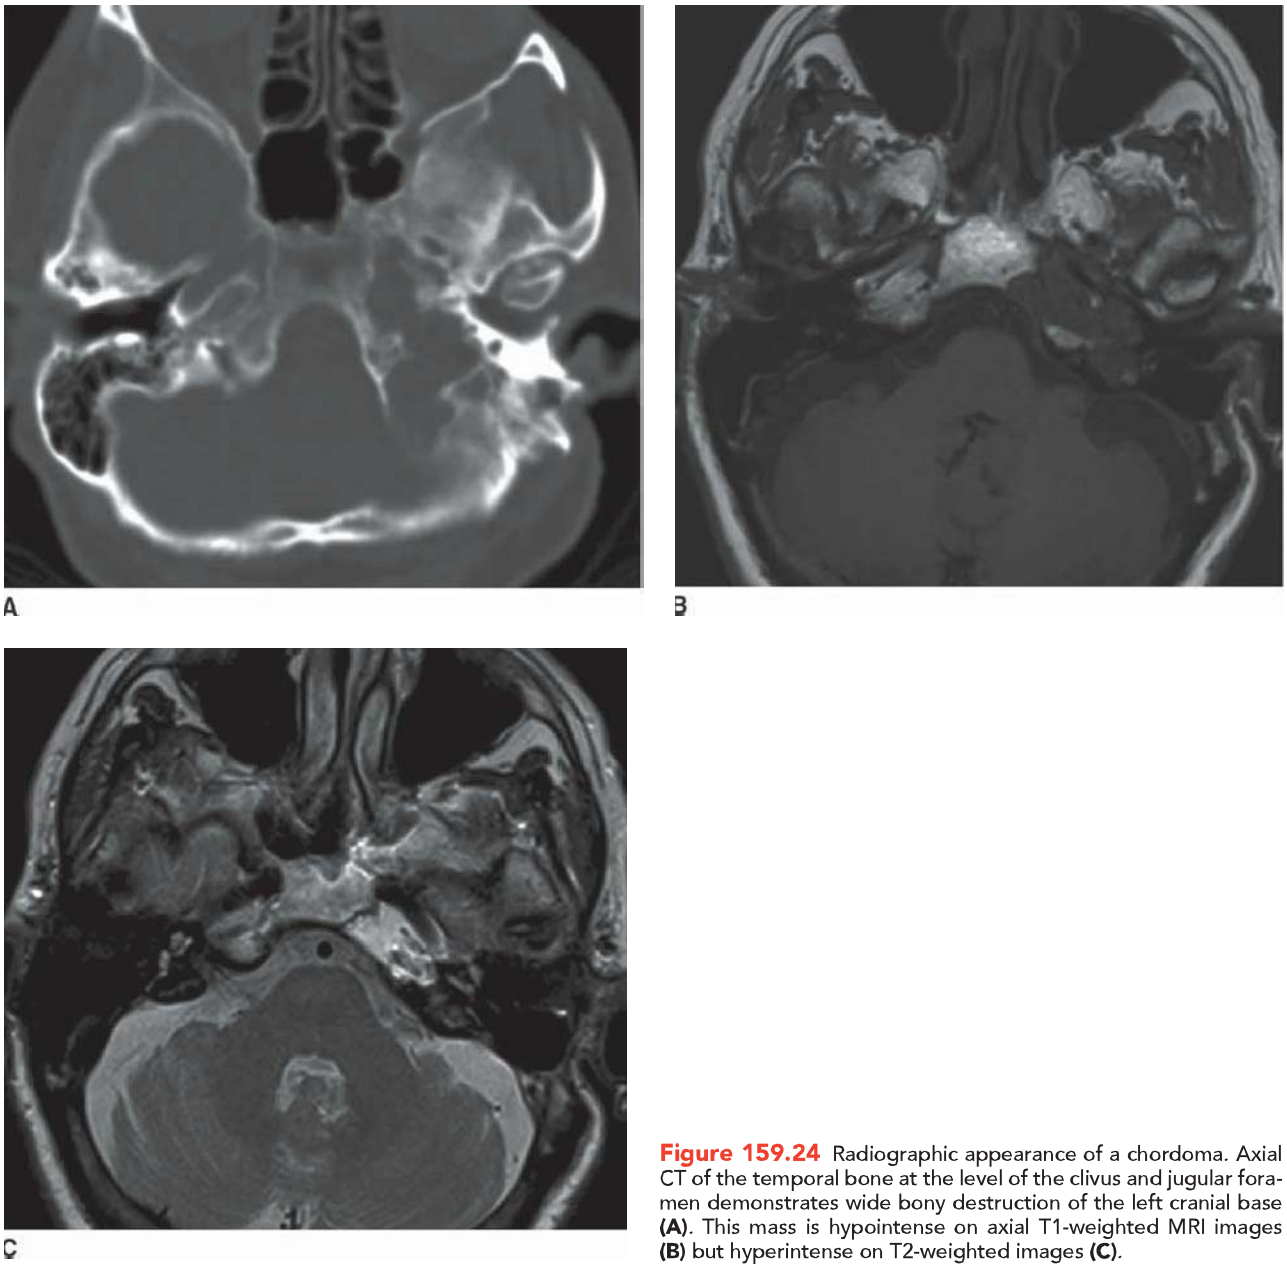

Figure 159.24 Radiographic appearance of a chordoma. Axial CT of the temporal bone at the level of the clivus and jugular foramen demonstrates wide bony destruction of the left cranial base **(A)**. This mass is hypointense on axial T1-weighted MRI images **(B)** but hyperintense on T2-weighted images **(C)**.

TABLE 159.2 CPA LESION RADIOLOGY SUMMARY

Lesion	T1 (Relative to Brain)	T2 (Relative to Brain)	Contrast Enhancement	CT	Other Findings
Cranial nerve schwannoma	Isointense	Isointense, with foci of high intensity	Strong, with cystic areas	• Smooth expansion of bone (IAC, jugular foramen, fallopian canal)	Fundal cap—VS Ice cream cone—VS
Meningioma	Isointense	Isointense	Strong	• Calcifications • Hyperostosis	
Paraganglioma	Isointense	Isointense	Strong	• Permeative erosion of bone • Erosion of caroticojugular spine	Salt and pepper appearance
Endolymphatic sac tumors	Hyperintense	Hyperintense	Strong	• Extensive bony destruction	Characteristic location
Metastases	Variable	Hyperintense	Strong, but heterogeneous	• Irregular bony destruction	Melanoma—T1 hyperintensity
Chordoma	Hypointense	Hyperintense	Moderate	• Central skull base destruction	Originate at the clivus
Chondrosarcoma	Hypointense	Hyperintense	Weak	• Irregular bony destruction • Calcified central matrix	Occur along petroclival suture
Epidermoid cyst (cholesteatoma)	Hypointense	Hyperintense	None	• Erosion of bone	Bright on T2 FLAIR Bright on DWI
Dermoid cyst	Hyperintense	Hyperintense	None	• Erosion of Bone • Calcification	Bright on T2 FLAIR
Arachnoid cyst	Hypointense	Hyperintense	None	• Sculpted bone	Dark on T2 FLAIR
Lipoma	Hyperintense	Hypointense	None	• Lower density than fluid	Suppresses with fat sat
Cholesterol granuloma	Hyperintense	Hyperintense	None	• Smooth expansion of bone	

SUMMARY

A variety of lesions may develop with the CPA. Many of the lesions may grow to substantial size without causing overt symptoms. Cranial neuropathies, most commonly seventh and eighth nerves, are common with lesions of the CPA. Due to the common clinical symptoms at presentation, imaging plays a vital role in differentiating these lesions, determining the extent of disease, and planning treatment. An review of imaging characteristics of these lesions is summarized in Table 159.2. These lesions may be addressed surgically through a variety of approaches that have been developed over the last century. The role of adjuvant therapy in disease of the cranial base is evolving and a multidisciplinary team approach to the treatment of complex cranial base lesions is beneficial to patient care and outcomes.

HIGHLIGHTS

- The CPA is an inverted triangle positioned between the pons and cerebellum within the posterior fossa and may contain pathologic lesions of the 5th to 12th cranial nerves, dura, and vasculature that may be infectious, inflammatory, immunologic, or neoplastic in origin.
- Lesions of the CPA can be classified by the site of origin (extraaxial vs. intraaxial) and imaging characteristics.
- Vestibular schwannomas are the most common lesions of the CPA and may cause unilateral tinnitus, sensorineural hearing loss, disequilibrium and are best demonstrated on MRI contrasted T1 sequences.
- NF2 is caused by mutations on chromosome 22 and characterized by bilateral vestibular schwannomas and may present with multiple CNS tumors such as cranial nerve schwannomas, meningioma, and ependymoma.
- Vestibular schwannomas can be observed clinically with serial MRI scans; however, the majority of tumors exhibit growth and predictors of growth include age at presentation, presence of tinnitus initially, cystic tumors, and growth demonstrated during first year after diagnosis.
- Stereotactic radiation is a viable option for treating vestibular schwannomas and may reliably halt tumor growth; however, minimizing cochlear radiation dose is necessary to limit long-term hearing loss. Radiation treatment of NF2-associated tumors results in a higher percentage of complications.
- Microsurgical resection of vestibular schwannomas may be accomplished safely and is primarily performed through a translabyrinthine approach; however, intracanalicular tumors less than 1.5 cm can be resected through a middle fossa approach in order to preserve hearing.

- Meningiomas within the CPA possess broad dural attachments and commonly engulf or adhere to adjacent cranial nerves.
- Epidermoid and dermoid cysts are hyperintense on T2-weighted images and may be distinguished from arachnoid cysts by their bright appearance on FLAIR sequences. Additionally, dermoid cysts are hyperintense on T1-weighted images.
- Other petrous apex lesions that possess inherent T2 hyperintensity include cholesterol granuloma, chondrosarcoma, and chordoma. Cholesterol granulomas exhibit T1 hyperintensity and smooth bony expansion. Chondrosarcomas erode bone and originate from the petroclival suture while chordomas originate from the clivus and exhibit smooth bony expansion.

Sudden Sensory Hearing Loss

160

Eric R. Oliver *George T. Hashisaki*

Sudden hearing loss is a startling and unsettling experience for the patient. Fortunately, most cases of sudden hearing loss are unilateral, and the prognosis for some recovery of hearing is good. For an unlucky few, the hearing loss can be severe and bilateral. Dilemmas in diagnosis make formulating a rational treatment plan an elusive process, and unfortunately, the diagnosis is commonly delayed. Patients stricken with sudden hearing loss are often frightened and desperate for a cure. There is an emotional burden carried by the physician to provide some definitive assistance. Because sudden hearing loss is a symptom common to many diseases, sifting through the myriad possibilities is a frustrating task.

DEFINITION

Sudden sensory hearing loss is a deceptively simple term, yet the concept defies strict definition. The terms sudden hearing loss, sudden sensory hearing loss, and sudden sensorineural hearing loss (SSNHL) each imply an acute insult of the cochlea and/or retrocochlear structures. Thus, the term SSNHL is perhaps the most accurate to denote this clinical entity. Various investigators have put forth definitions based on the severity, time course, and frequency spectrum of the loss, as well as specific audiometric criteria. The most commonly used definition is a 30-decibel (dB) or greater sensorineural loss over three contiguous frequencies occurring within 3 days (1). Abrupt and rapidly progressive losses have both been encompassed under a single definition. Awakening with a hearing loss, hearing loss noted over a few days, selective low- or high-frequency loss, and distortions in speech perception have all been classified as SSNHL. Taking a broad-minded view, let us consider any noticeable and measurable loss of hearing function—pitch or speech perception—occurring over a matter of minutes to days as a sudden hearing loss. Also, SSNHL encompasses definite etiologies as well as idiopathic causes.

EPIDEMIOLOGY

Estimates of the annual incidence of sudden SSNHL range from 5 to 20 cases per 100,000 persons (2). Because many patients do not seek medical attention after spontaneous resolution, and others are misdiagnosed initially, this incidence figure is an underestimate. Likely, there is an equal distribution of female-to-male cases. Cumulative data from several studies show a slight male preponderance at 53% (1,530/2,864) (2–8); however, another large study of 1,220 patients noted a slight female preponderance, without specifying numbers (9). Gender does not seem to be a risk factor. Several studies have not delineated right versus left ears affected, other than to state an equal distribution. Curiously, from combined study data, it was found that hearing loss affected more left ears (55%) (2–5,7,10). An equal distribution between ears would be expected. Bilateral sudden hearing loss occurs in about 1% to 5% of cases (3–5,7,9–11). Sudden hearing loss occurs in all age groups, but fewer cases are reported in children or the elderly (2,5,6). Middle-aged and young adults experience similar incidence rates (2,5,6,9). The median age at presentation ranges from 40 to 54 years (3–6,8). Acute tinnitus accompanies the hearing loss in most cases, and vestibular symptoms are present in one-fourth to half of patients (3–6,8).

DIFFERENTIAL DIAGNOSIS

SSNHL can be divided into categories of defined causes and idiopathic sudden sensorineural hearing loss (ISSNHL). Defined causes of SSNHL are varied and less common (Table 160.1). Approximately 10% to 15% of cases are due to an identifiable etiology (3,5,12,13). Three main theories exist to explain ISSNHL: viral infection, vascular compromise, and intracochlear membrane rupture. There is additional evidence to support a fourth explanation:

TABLE 160.1 DIFFERENTIAL DIAGNOSIS IN SUDDEN SENSORINEURAL HEARING LOSS

Category	Etiology
Infection	Viral cochleitis, labyrinthitis, or cranial nerve VIII neuropathy
	Herpes simplex
	Mumps
	Varicella zoster (Herpes zoster oticus)
	Rubella
	Influenza
	Epstein-Barr
	Enterovirus
	Cytomegalovirus
	HIV
	Meningitis
	Syphilis
	Lyme disease
Inflammation	Autoimmune
	Cogan syndrome
	Behcet syndrome
	Systemic lupus erythematosus
	Multiple sclerosis
Trauma	Temporal bone fracture
	Acoustic trauma
	Barotrauma
	Perilymph fistula
Neoplasm	Vestibular schwannoma
	Meningioma
	Temporal bone metastasis
	Carcinomatous meningitis
Toxins	Aminoglycosides
	Aspirin
	Cisplatin
	Radiation therapy
Cardiovascular	Thromboembolism
	Macroglobulinemia
	Sickle-cell disease
	S/P coronary bypass graft surgery
	Severe acute hypotension
Otologic	Endolymphatic hydrops
	Meniere disease
Genetic	*GJB2* mutation (*DNFB1*; encoding connexin 26)
	Enlarged vestibular aqueduct in Pendred syndrome
	Branchio-otorenal syndrome
	Renal tubular acidosis
	Fabry disease

autoimmune inner ear disease. With sudden hearing loss as a symptom, a disease process could involve any of these theoretical possibilities. Each theory may explain a number of episodes of SSNHL.

VIRAL INFECTION

Considerable circumstantial evidence implicates viral infection as one cause of ISSNHL. From studies of patients with ISSNHL, this trail of evidence can be traced from reports of a high prevalence of a recent viral type of illness, through evidence of recent viral seroconversion, to temporal bone histopathology. The weakest of these links is the associated history of a recent viral illness. Noncontrolled studies report that 17% to 33% of patients recall a recent viral illness (3,9). Lest those numbers seem significant, 25% of healthy patients visiting an otolaryngology clinic had experienced a potential viral illness within a month preceding the visit (14). Wilson provided good evidence of viral seroconversion by comparing patients experiencing ISSNHL with control patients. Rates of seroconversion for the herpesvirus family were significantly higher in the sudden-hearing-loss population (15). Finally, temporal bone histopathologic studies of patients who experienced ISSNHL found damage in the cochlea consistent with viral injuries (16–19). Loss of hair cells and supporting cells, atrophy of the tectorial membrane, atrophy of the stria vascularis, and neuronal loss were seen; these patterns were similar to findings in documented cases of mumps-, measles-, and maternal rubella–related hearing loss. Viral infection can be implicated as a cause of ISSNHL, but it cannot as yet be proved.

VASCULAR COMPROMISE

The cochlea derives its blood supply from the labyrinthine artery, with no collateral vasculature. Cochlear function is exquisitely sensitive to changes in blood supply (20). Thus, vascular compromise of the cochlea caused by thrombosis, embolus, reduced blood flow, or vasospasm would seem a likely etiology for ISSNHL. The abrupt or rapid time course in sudden hearing loss correlates well with a vascular event. A reduction in oxygenation of the cochlea is the likely consequence of alterations in cochlear blood flow. Alterations in perilymph oxygen tension have been measured in response to changes in systemic blood pressure or intravascular carbon dioxide partial pressure (PCO_2) (21). Histologic evidence of cochlear damage following occlusion of the labyrinthine vessels was documented in temporal bone studies in both animals and humans (19,22). Intracochlear hemorrhage was noted as an early development; subsequently, fibrosis and ossification of the cochlea evolved. It remains unproven whether SSNHL is associated with common cardiovascular risk factors. An association between SSNHL and hypercholesterolemia was revealed in a few case-control series (23–25). SSNHL may be more common and severe in patients with diabetes (26).

INTRACOCHLEAR MEMBRANE RUPTURE

Thin membranes separate the inner ear from the middle ear, and within the cochlea, delicate membranes separate the perilymphatic and endolymphatic spaces. Rupture of either or both sets of membranes theoretically could produce a sensory hearing loss. A leak of perilymph fluid into the middle ear via the round window or oval window has

been postulated to produce hearing loss by creating a state of relative endolymphatic hydrops or by producing intracochlear membrane breaks. Rupture of intracochlear membranes would allow mixing of perilymph and endolymph, effectively altering the endocochlear potential. Simmons (27) favored the theory of intracochlear membrane rupture, as did Goodhill and Harris (28); histologic evidence was documented by Gussen (29).

AUTOIMMUNE INNER EAR DISEASE

Sensorineural hearing loss induced by an autoimmune process has gained greater acceptance since the concept was introduced in 1979 by McCabe (30). Progressive sensorineural loss is seen with this condition. Whether or not SSNHL occurs with autoimmune inner ear disease is unclear, but immunologic activity in the cochlea is supported by an expanding body of evidence. The association of hearing loss in Cogan syndrome, systemic lupus erythematosus, and other autoimmune rheumatologic disorders has been well documented.

EVALUATION

Patient evaluation should proceed promptly and expeditiously. Early presentation to a physician and early institution of treatment improve the prognosis for hearing recovery (2,3,5,9). A diligent search for a treatable or defined cause of the sudden hearing loss is an immediate goal. Information about the onset, time course, associated symptoms, and recent activities may give helpful clues. Reviewing the past medical history, especially risk factors for hearing loss, is necessary. All medications, including over-the-counter products, must be delineated. A thorough head and neck examination, with special attention to the otologic and neurologic examination, is a requisite. Pneumatoscopy, in search of a fistula sign, should be included. A cardiovascular examination should also be performed to evaluate for atrial fibrillation, aortic and mitral valve pathology, and carotid bruits.

Pure tone and speech testing are mandatory components of the audiometric evaluation of SSNHL. Immittance (tympanometry and acoustic reflex) testing is recommended to assess for changes in middle ear compliance not visible on otoscopic examination. Auditory brainstem response (ABR) and otoacoustic emissions (OAEs) testing may provide additional information regarding the integrity of the auditory system. The presence of measurable OAEs indicates preservation of some outer hair cell function. The ABR reflects function of the retrocochlear neural pathways. The ABR and OAE results also may assist in diagnosing a functional hearing loss. Vestibular tests are obtained when indicated by the history and physical examination. An exhaustive set of laboratory tests would be overwhelmingly costly. One approach is to obtain those laboratory tests for which the results may influence the treatment plans (Table 160.2).

TABLE 160.2 LABORATORY TESTS AND RADIOGRAPHIC IMAGING IN SUDDEN SENSORINEURAL HEARING LOSS

Test	Purpose
CBC with differential	Polycythemia, leukemia, thrombocytosis
Sedimentation rate, ESR	Screen for autoimmune or inflammatory disease; follow with ANA or 68 kD Ab test
FTA-Abs or MHA-TP	Antibody test, *Treponema pallidum*, congenital or acquired
Coagulation studies	Coagulopathy (if indicated, by history)
Thyroid function tests	Hypothyroidism (if indicated, by history)
MRI	Retrocochlear lesion, multiple sclerosis, intracochlear hemorrhage
CT scan	Otic capsule abnormalities in pediatric patients

68 KD Ab, 68 kiloDalton antibody; ANA, antinuclear antibody; CBC, complete blood count; ESR, erythrocyte sedimentation rate; FTA-Abs, fluorescent treponemal antibody-absorption test; MHA-TP, microhemagglutination-*Treponema pallidum*; MRI, magnetic resonance imaging; CT, computed tomography.

At some point during the evaluation and treatment process, an imaging study of the internal auditory canal (IAC) and cerebellopontine angle (CPA) is advised. Approximately 0.8% to 4% of patients with ISSNHL have been diagnosed with IAC or CPA tumors (2,3,9,31–34). A gadolinium enhanced magnetic resonance imaging (MRI) scan is the optimal study to identify IAC and CPA lesions; alternatively, a neurodiagnostic ABR (if hearing levels permit) could be used as a screening test. In addition, MRI scanning can demonstrate evidence of demyelination, intracochlear hemorrhage, or vascular abnormalities (32–35). In younger patients, for whom there is only a small possibility of a vestibular schwannoma but a greater possibility of an anatomic abnormality, a noncontrast temporal bone computed tomography (CT) scan could be obtained. Anatomic defects such as cochlear dysplasia, Mondini malformation, or an enlarged vestibular aqueduct might account for a sudden hearing loss (36).

Because SSNHL is often accompanied with the sensation of aural fullness, the hearing loss is often attributed to the more common conditions of cerumen impaction, acute upper respiratory tract infection with associated middle ear dysfunction, or allergy by primary care providers, and no further investigation is performed. Because a delay in diagnosis and treatment can negatively impact the ultimate hearing outcome, it is essential that all health care providers are capable of differentiating SSNHL from other routine presentations of acute hearing loss. Testing with a 512 Hz tuning fork is very valuable in categorizing the hearing loss as conductive or sensorineural. Referral to an otolaryngologist and audiometric testing should proceed for any patient with a suspected SSNHL.

TREATMENT

The treatment regimens for ISSNHL are legion, and this diversity reflects both the different etiologies that may cause sudden hearing loss and the uncertainty in diagnosis. Primary treatment is guided by the specific cause, if one is identified. As discussed previously, no specific cause is identified in the vast majority of cases, and empirical treatments can be considered. These therapies can be grouped by mechanism of action: (a) anti-inflammatory agents, (b) vasodilators, (c) rheologic agents, (d) antiviral agents, (e) diuretics, (f) triiodobenzoic acid derivatives, (g) hyperbaric oxygen, and (h) surgery.

Anti-inflammatory Agents

Corticosteroids are the primary anti-inflammatory agents used to treat ISSNHL. The mechanism of action of corticosteroids in SSNHL is unknown, although reduction of cochlea and auditory nerve inflammation is the presumed pathway. The typical dosing of oral corticosteroids for SSNHL (prednisone, 1 mg/kg/d, usual maximum 60 mg/day) is tapered over a period of 10 to 14 days. Steroids may also be directly injected into the middle ear space through the tympanic membrane (intratympanic delivery) to permit perfusion into the inner ear via the round window.

Vasodilators

Theoretically, vasodilators improve the blood supply to the cochlea, reversing hypoxia. Histamine, nicotinic acid, papaverine, procaine, niacin, and carbogen have been used in attempts to improve cochlear blood flow. Carbogen (5% carbon dioxide and 95% oxygen) inhalation has been shown to increase perilymph oxygen tension (20,37).

Rheologic Agents

Altering blood viscosity to improve blood flow and oxygen delivery has been the theory behind the use of low-molecular-weight dextrans, pentoxifylline, and the anticoagulants heparin and warfarin. Dextrans cause a hypervolemic hemodilution and affect factor VIII, both effects influencing blood flow. Pentoxifylline allows greater platelet deformability, and anticoagulants interfere with the coagulation cascade.

Antiviral Agents

Acyclovir and amantadine have had limited use in treating ISSNHL, presuming a viral etiology. Famciclovir and valacyclovir are newer agents, similar in structure and activity to acyclovir. Both of these medications have a three-times-daily dosing schedule, as compared to the five-times-daily schedule for acyclovir.

Diuretics

Under the assumption that some episodes of ISSNHL are secondary to cochlear endolymphatic hydrops, diuretic therapy has been used as treatment. As in Ménière disease, the mechanism of action for diuretics in sudden hearing loss is not understood.

Triiodobenzoic Acid Derivatives

These agents are thought to affect the stria vascularis and assist in maintaining the endocochlear potential (8). Diatrizoate meglumine, an angiographic contrast agent, is the most commonly used derivative of triiodobenzoic acid.

Hyperbaric Oxygen Therapy

Therapeutic administration of 100% oxygen at environmental pressures greater than one atmosphere absolute has been proposed to improve ISSNHL by increasing the partial pressure of oxygen delivered to the inner ear. Treatments typically consists of pressurization and administration of 100% oxygen for 1 to 2 hours once or twice daily. A typical course will consist of 20 to 40 treatments (38).

Surgery

Repair of oval and round window perilymph fistulae has been used in cases of ISSNHL associated with a positive fistula test or a history of recent head trauma or barotrauma. Perilymph leaks could produce sudden hearing loss in accordance with the intracochlear membrane rupture theory. Alternatively, low perilymph pressure caused by a fistula could produce a state of relative cochlear endolymphatic hydrops.

RESULTS

Spontaneous recovery rates for SSNHL are generally good. Published rates range from 47% to 63%, combining categories of complete and good or partial recovery (1,5,39). Mattox and Simmons defined complete recovery as a pure-tone average (PTA) less than 10 dB or equaling the uninvolved ear, and good recovery as a PTA less than 40 dB or more than 50 dB improvement from the initial audiogram (5). The recovery rate for these two groups was 63%. For Wilson et al. (1), complete recovery was defined as recovery to within 10 dB of the prehearing loss speech reception threshold (SRT) or PTA. Partial recovery was defined as recovery to within 50% of the prehearing loss SRT or PTA. The unaffected ear was used to establish preexisting hearing levels for the involved ear. Fifty-two patients who had follow-up without treatment had a 58% spontaneous recovery rate. When combined with the placebo group in their study, the spontaneous recovery rate was 47%. Chen et al. (39) found similar rates of spontaneous recovery in

their untreated patients, using either the criteria of Mattox and Simmons (5) or Wilson et al. (1).

A review of outcomes for the various therapeutic regimens gives conflicting results. Heterogeneity of inclusion and exclusion criteria, recovery definitions, and follow-up duration confound an accurate comparison of studies. Many studies lack control patients. Selection bias could influence measured outcomes; tertiary referral centers might accrue a different profile of patients than other practices, with some patients having a longer duration of symptoms or more severe hearing losses. Several studies using vasodilator therapy as a component of treatment failed to show significant differences from placebo (4,14); however, Fetterman et al. (3) reported their best recovery results: 63% improved to a PTA greater than 10 dB or speech discrimination greater than 15% when treatment included vasodilators. Based on controlled studies, few data support vasodilator therapy. Studies including low molecular weight dextrans or pentoxifylline did not demonstrate recovery rates better than placebo (7,10,40). Redleaf et al. (8) reported 64% of patients improving, however. They also used diatrizoate therapy, and there was no placebo arm in the study. Cochrane database systematic reviews found no significant role for vasodilator and vasoactive treatments (41), but noted an increased rate of a 25% increase in pure tone average after hyperbaric oxygen therapy (38). However, the authors urged caution when interpreting this result, due to methodologic weaknesses and low patient numbers in the included studies.

Corticosteroid therapy has shown widely varying outcomes. Published recovery rates range from 41% to 61% (1–4,10,39,40). Wilson et al. (1) demonstrated a significant improvement, finding 61% improved on oral steroids compared with a 32% improvement rate on placebo. They stratified their patient groups by audiometric patterns and determined that hearing losses between 40 and 90 dB responded better to steroid therapy; 78% in this severe loss group improved. However, the rate of improvement in the corticosteroid treated cohort was similar to the recovery rate in patients who did not receive treatment in other reports (5,40). Chen et al. (39) also found a significant benefit with oral steroids in a study of 318 patients. They found the greatest magnitude of improvement in patients with greater than 60 dB PTA hearing loss, citing a "floor effect" limiting the degree of improvement in mild hearing losses. Because of the "floor effect," a benefit of oral steroids might be present in those with mild hearing loss, but the effect could not be proven.

A recent Cochrane Review (42), systematic review (43), and meta-analysis (44) each concluded that the efficacy of oral corticosteroid therapy for SSNHL remains unproven. There are limited data comparing various doses or duration of oral corticosteroid therapy. Studies that investigated the correlation between the duration of SSNHL before treatment and hearing outcomes have reported the greatest hearing recovery when oral steroids are initiated within the first 1 to 2 weeks after hearing loss onset, and minimal to no benefit when initiated 4 or more weeks after the onset of symptoms (2,3,45).

Transtympanic steroid application has theoretical benefits of a high delivery concentration to the inner ear and low systemic concentrations. Several studies have addressed the efficacy of transtympanic steroid treatment, but because of differences in delivery technique, corticosteroid, dose, and dosing schedule, direct comparisons are difficult (46–48). Using a transtympanic injection of dexamethasone, Chandrasekhar found that 8 of 11 ears treated had some hearing improvement. The mean SRT improved by 9 dB and the mean speech discrimination or word recognition score (WRS) improved from 61.5% to 77.3% (46). Kopke et al. placed a microcatheter into the round window niche through a tympanomeatal flap and perfused the niche with methylprednisolone. For six patients treated within 4 weeks of the onset of the hearing loss, all experienced some hearing return. The mean PTA improved 50.8 dB, and the mean WRS improved from 1.3% to 62.2% (47). Gianoli and Li applied topical steroids through a ventilation tube in the tympanic membrane. Hearing improvement was seen in 44% (10 of 23 patients) (48). Applying dexamethasone through a porous wick placed inside a ventilation tube, Light and Silverstein found a 10 dB improvement in PTA for 23% and a 15% improvement in speech discrimination for 35% in a study of 48 patients. For the patients experiencing a hearing improvement, the mean PTA improved 43% and the mean WRS improved 51% (49). Haynes et al. investigated transtympanic treatment after failure of systemic oral therapy. With a definition of improvement of 20 dB PTA, the recovery rate was 27.5%. Dramatic hearing recovery in treatment failures was rarely encountered (50).

A multicenter randomized trial comparing the efficacy and safety of oral and intratympanic corticosteroids for primary therapy of unilateral ISSNHL involving 250 patients was recently completed (51). Participants were followed for 6 months. One hundred and twenty-one patients received 60 mg/day of oral prednisone for 14 days with a 5-day taper, and 129 patients received 4 doses over 14 days of 40 mg/mL of methylprednisolone injected into the middle ear. In the oral prednisone group, PTA improved by 30.7 dB compared with a 28.7-dB improvement in the intratympanic treatment group. Recovery of hearing on oral treatment at 2 months by intention-to-treat analysis was 2.0 dB greater than intratympanic treatment. The authors concluded that transtympanic therapy is not inferior to oral steroids. However, oral steroids offer a significant cost advantage over transtympanic delivery.

Given the theoretical implication of viral infection as a cause of ISSNHL, the use of antiviral therapy for ISSHL is a logical extension. A multicenter, randomized, prospective, double-blind trial comparing prednisolone against prednisolone and acyclovir did not show a significant beneficial effect of acyclovir (52). The study size was not large, having 22 patients in each arm of therapy. In patients treated with corticosteroids alone, 80% demonstrated at least a 10-dB

PTA improvement. Tucci et al. (53) did not find a significant benefit from the addition of valacyclovir to concurrent oral prednisone therapy in a larger multicenter, randomized, prospective trial. Two additional studies found no benefit from the addition of antiviral therapy (54,55). Two studies using diatrizoate were reviewed. Wilkins et al. (10) found no significant difference in recovery using diatrizoate in a multidrug regimen, compared with spontaneous recovery rates (1,5). Redleaf et al. (8), using diatrizoate and dextran, reported a beneficial effect: 64% of patients had improvement. Interestingly, using the hearing recovery criteria of Wilkins et al. (10), recalculated data from the Redleaf study indicated only a 36% recovery rate to a classification of complete or good.

Controversy regarding the results of surgical repair of perilymphatic fistulae continues. A universal standard for positive identification of a fistula has not been achieved. Without uniform standards, outcomes of surgical repair are difficult to compare.

PROGNOSIS

Prognostic factors affecting outcome have been postulated. The associated symptoms of vertigo or imbalance seem to portend a lower recovery rate (1–3,8,9). Two studies, in addition, found severe vertigo associated with more cases of high-frequency or profound hearing loss (5,6). This association could be explained anatomically by the close proximity of the basal turn of the cochlea to the vestibule (6). Patient age also may impact recovery, although there are less consistent data across studies. The youngest and the oldest patients may have lower recovery rates.

The likelihood of recovery of hearing has been reported to vary with the severity of hearing loss at presentation and the configuration of the audiogram. Patients with mild losses typically achieve complete recovery, while those with moderate losses often partially recover spontaneously, but rarely realize full recovery unless treated. Those with severe-to-profound hearing losses rarely improve spontaneously or recover fully (1,2,5). Low frequency losses and flat or downward sloping audiograms were associated with a worse prognosis in some studies (5,9,11). Patients with poorer initial WRS, lower initial thresholds at 4,000 Hz, and younger age were more likely to respond to treatments in another study (3). The prognosis for recovery of hearing seems to be worse in older patients and those with associated vestibular symptoms (2,3,5,6,9). The sooner a response is seen, the better the overall prognosis. Patients in whom there is no audiometric improvement within 2 weeks of presentation are unlikely to demonstrate much recovery (56).

CONCLUSIONS

SSNHL remains a puzzling affliction. Given the rate of spontaneous recovery, the prognosis for some hearing recovery is good. It is likely that selection bias affects most studies of ISSNHL; patients with sudden hearing loss and spontaneous recovery within a few days probably will not seek medical evaluation. The true spontaneous recovery rate is unknown.

Treatment should be based on a rational approach. Should no definite or treatable etiology be found, the treatment regimen is dictated by the most likely factors involved. Remembering that the medications used in treatment of SSNHL have potential side effects and the dictum, "Do no harm," the physician and patient must agree on the best course of action.

HIGHLIGHTS

- Sudden sensory hearing loss occurs at an annual incidence of 5 to 20 cases per 100,000 population. Some cases resolve spontaneously and medical attention is not pursued; therefore, the true incidence rate is likely higher.
- The prognosis for some recovery of the hearing loss is good. The spontaneous recovery rate may be as high as 63%.
- There are three generally accepted theories for the pathogenesis of ISSNHL. Viral infection, vascular compromise, and intracochlear membrane breaks are thought to explain most episodes that defy a clear cause. A fourth entity, autoimmune inner ear disease, also may add to the number of cases.
- The evaluation of patients with sudden hearing loss should include a thorough history and physical examination. A diligent search for treatable causes of the hearing loss is very important. Laboratory tests can be useful for this purpose.
- Because 0.8% to 4% of patients presenting with SSNHL may have a CPA mass, a retrocochlear evaluation using MRI with gadolinium or ABR is warranted.
- Many treatment regimens exist, and the rationale behind any particular therapy employed should be understood.
- Since there may be only a 2 to 4 week window for effective treatment of SSNHL, it is important to start therapy as soon as possible.
- There is no single treatment of choice for ISSNHL. Many diseases produce sudden hearing loss, and the treatment should be directed toward the most likely causes.
- Frontline health care workers who encounter patients with complaint of acute hearing loss should determine its character as either conductive or sensorineural, and carry a low threshold for audiometric testing and otolaryngology consultation.

Tinnitus and Hyperacusis

161

Maura K. Cosetti *Pamela C. Roehm*

Tinnitus, or the perception of sound in the absence of an external auditory source, is a common patient complaint in otolaryngologic practices. Recent studies estimate that tinnitus may affect up to 50 million adults in the United States, with 16 million experiencing frequent or chronic tinnitus in the prior 12 months (1,2). The distinction between nonpulsatile and pulsatile tinnitus and subjective and objective tinnitus are critical in the appropriate diagnosis and management of these patients. This chapter discusses the theories of pathophysiology, epidemiology, assessment tools, and diagnostic and therapeutic considerations associated with each type of tinnitus. As hyperacusis frequently presents in conjunction with nonpulsatile subjective tinnitus, we include a discussion of this condition along with that form of tinnitus. Unfortunately, tinnitus, particularly the more common nonpulsatile subjective form, is frequently dismissed due to the mistaken belief that there is no available therapy for these patients; tinnitus patients are instructed that there is "no pill or surgery" to help them and subsequently discharged. In this chapter, we discuss the various forms of tinnitus, and rational guidelines for their diagnosis and management.

HISTORY AND PHYSICAL EXAMINATION

Classification

Although a variety of tinnitus classification systems have been proposed, there is no currently accepted system in widespread use. At present, the most clinically relevant distinction for the general otolaryngologist is the characterization of subjective versus objective and pulsatile versus nonpulsatile tinnitus. Classification of a patient's tinnitus into these different categories can aid in appropriate diagnosis and management of his or her complaint, and so the patient's history and physical examination should be structured to first determine the answers to these critical questions.

The distinction between pulsatile and nonpulsatile tinnitus is based on the patient's description of the sound that he or she perceives. Further discrimination of pulsatile sounds into arterial (pulsations following the heartbeat) or venous ("whooshing" sounds) can also be based on the patient's description. The distinction between subjective (heard only by the patient) and objective (able to be heard by patient and examiner) is also critical in diagnosis and treatment of tinnitus and is made during the physical examination (3). Objective tinnitus can occasionally be heard without other instrumentation by the clinician (as in patients with tinnitus resulting from mechanical cardiac valves). More commonly, the sound is perceived on auscultation of the periauricular region, ear canal, neck, or chest. Patient confirmation that the sound in question is identical to their tinnitus is required for definite identification. Objective tinnitus is rare and suggests an identifiable source for the acoustic stimulus underlying the tinnitus, such as a vascular bruit, vascular tumor, and palatal or tensor tympani myoclonus (4).

Pulsatile tinnitus can be either subjective or objective, while nonpulsatile tinnitus is almost exclusively subjective. Patients' descriptions of both pulsatile and nonpulsatile tinnitus can vary significantly, so clinical acumen is often required to effectively characterize the type of tinnitus. Typically, nonpulsatile tinnitus is described as "ringing," "hissing," "buzzing," or "roaring." In contrast, sounds characterized as rhythmic, concordant with the patient's pulse, modified by external movements, or altered by changes in position should be classified as "pulsatile" tinnitus.

History

A careful and accurate history of the present illness is crucial for tinnitus characterization and has important implications in both diagnosis and therapeutic management. In addition to differentiating pulsatile from nonpulsatile

tinnitus, the history should clarify the location, that is, unilateral or bilateral, onset, duration, intensity, and other elements of the quality of the perceived sound. Modifying factors, such as external movements or position changes, should be identified. Patients complaining of pulsatile tinnitus should be directly asked if the pulsations of their tinnitus concords with their pulse (5). Review of systems should include questioning regarding the patient's mood and sleep patterns, particularly for patients complaining of subjective nonpulsatile tinnitus.

A complete otologic history should be obtained from every tinnitus patient, including associated symptoms of hearing loss, otalgia, otorrhea, autophony, vertigo, imbalance, disequilibrium, and other neurologic symptoms. Past medical history should include prior history of otitis media, otologic or neurosurgical procedures, head trauma, meningitis, exposure to ototoxic medications (including antibiotics, chemotherapeutic agents, and nonsteroidal anti-inflammatory medications), history of autoimmune diseases, and current or prior psychiatric disorders. A list of current medications, including vitamins, herbal supplements, and over-the-counter medications, is necessary. Finally, the clinician should inquire about pertinent family history, such as paragangliomas. Social history should include tobacco, alcohol, illicit drug usage, and intake of caffeine, all of which can cause or increase nonpulsatile tinnitus. Levels of previous noise exposure should be determined.

Physical Examination

A complete head and neck exam should be performed, including otoscopy (by binocular microscopy), pneumatic otoscopy, and tuning fork exam (both the Weber and Rinne). The tympanic membrane should be closely observed for medial and lateral excursions associated with breathing. Patients should be monitored for torsional nystagmus during pneumatic otoscopy (fistula test), preferably with Frenzel lenses in place. The patient should be questioned for vertigo induced during pneumatic insufflation of the ear canal (Hennebert symptom). Cranial nerves should be tested. Additional elements of a neurotologic examination, including cerebellar function, gait evaluation, Romberg and Fukuda testing, and positional testing, should be performed when appropriate.

For patients complaining of pulsatile tinnitus, palpation of the postauricular region, mastoid, and neck should note any thrills or vascular cords. Auscultation of periauricular region, neck, and chest should note the presence of objective tinnitus as well as the presence of any bruits, vascular hums, or murmurs. Light ipsilateral and bilateral neck compression should be performed to assess the effect of decreased jugular venous flow on presence or intensity of the pulsatile tinnitus. In young patients, carotid artery compression can also be attempted with the goal of differentiating venous from arterial causes of pulsatile tinnitus. Careful exam of the temporomandibular joint and ipsilateral pterygoid muscles should note any tenderness, clicking, or inflammation. Palpation of the pre- and supraauricular regions should assess for parotid abnormalities or masses. Flexible fiberoptic nasopharyngoscopy should be performed when examination of the eustachian tube (ET) orifice is warranted or when palatal myoclonus is suspected.

Diagnostic Evaluation

The initial evaluation of a patient presenting with tinnitus should include a complete audiogram, including puretone and spondee thresholds, word recognition scores, and tympanometry. Often it is useful to perform this test prior to evaluation in the otolaryngologist's office, as it is critical in the determination of the etiology of tinnitus and appropriate therapy. Other audiologic tests, including immittance testing, auditory brainstem responses, otoacoustic emissions, and high-frequency audiograms, may be useful in evaluation of select patients with tinnitus. Testing for vestibular function, (vestibular evoked myogenic potentials [VEMPs], videonystagmography [VNG], and rotational chair testing) may be warranted in the evaluation of patients with specific complaints and findings on physical examination, as discussed below. Similarly, imaging studies may be indicated for certain patients who present with tinnitus, but are not required for all.

SUBJECTIVE NONPULSATILE TINNITUS

Etiology

A variety of clinical entities may underlie nonpulsatile tinnitus. Most often, these conditions cause hearing loss, which is thought to be the initial step in the generation of tinnitus in these patients. Noise-induced hearing loss, presbyacusis, ototoxic medications, labyrinthitis, herpes zoster oticus, Meniere's disease, and genetic hearing losses cause inner ear hair cell damage resulting in hearing loss, which can lead to nonpulsatile tinnitus. Chronic otitis media, cholesteatoma, canal occlusion, and otosclerosis can cause a conductive hearing loss that ultimately may result in tinnitus. Lesions that affect the cochlear nerve and central nervous system (CNS) such as acoustic neuroma, meningioma, multiple sclerosis, and Charcot-Marie-Tooth disease can also induce tinnitus, typically along with a coincident hearing loss (Fig. 161.1, Table 161.1).

However, not every patient with a hearing loss will have tinnitus. Additionally, patients without a discernable hearing loss (including evaluation with a high-frequency audiogram) or other identifiable pathology may suffer from tinnitus as well. Other primary causes of tinnitus include pharmacologic or dietary stimulants, head trauma, and psychiatric disorders. Drugs or stimulants

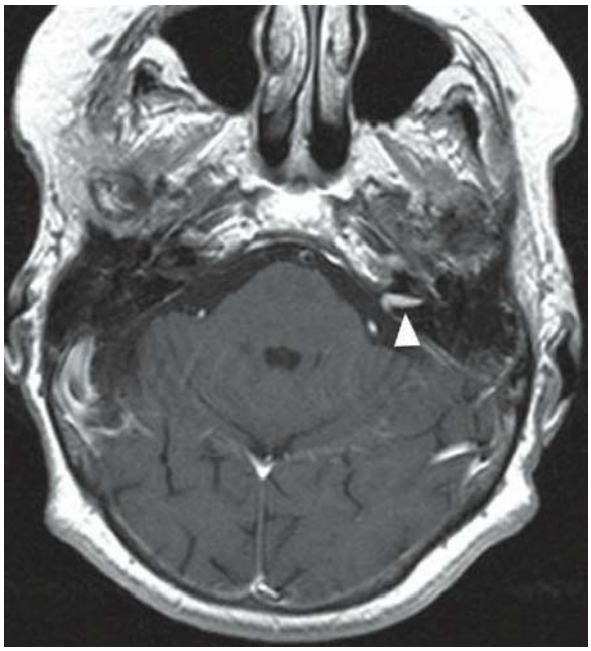

Figure 161.1 Axial contrast-enhanced MRI shows left vestibular schwannoma (*white arrowhead*) that was causing nonpulsatile tinnitus.

which increase neural firing, such as aspirin, nonsteroidal anti-inflammatory medication, nicotine, ethanol, and caffeine, can cause or exacerbate nonpulsatile tinnitus (Table 161.2).

The underlying mechanism of nonpulsatile subjective tinnitus, including the generator of the noise, has not yet been described. Advances in experimental and imaging techniques have revealed significant insights into the etiology of this disorder. These insights may ultimately guide rational treatment of this form of tinnitus.

Initial theories of the generation of nonpulsatile tinnitus focused on the role of the cochlea, specifically the role of certain cochlear structures such as outer hair cells. These theories flowed logically from observations that subjective nonpulsatile tinnitus is frequently seen in individuals with measurable hearing loss or following known ototoxic injuries (such as ototoxic medication exposure, noise exposure, head injury). However, later findings, such as the persistence of tinnitus following truncation of the auditory nerve or ablation of the cochlea, disproved these exclusively cochleogenic etiologies for the majority of sufferers of subjective nonpulsatile tinnitus (6–8).

More recently, imaging studies on humans with tinnitus and animal studies have revealed changes in neural activity and connectivity throughout the auditory system following loss of hearing. The spontaneous firing rate of auditory neurons increases during tinnitus, a phenomenon that may generate the tinnitus sound (9,10). Another possibility is that increased synchrony of firing within auditory pathway neurons may be perceived as tinnitus (9,11). Many studies have noted a decrease in inhibitory neural input at multiple sites along the central auditory pathways, including the dorsal cochlear nucleus (12–15). This leads to a net increase in excitatory signaling in the auditory pathway and has been proposed as the neurophysiologic basis for subjective tinnitus.

Others have proposed that neuronal plasticity may lead to tinnitus. Following hearing loss, studies in animals and humans have demonstrated a change in the tonotopic map throughout the auditory system. Some have proposed that these plastic changes in the frequency representation in areas of the brain and brainstem are the origin of tinnitus, while others have suggested that these changes in the tonotopic map are merely epiphenomena of that hearing loss (16). Many other plastic changes also follow

deafferentation of areas of the auditory system, including changes in synaptic structure and firing patterns, formation of new synapses and elimination of others, and dendritic branching. All of these changes may underlie the complaint of nonpulsatile tinnitus (16).

None of these etiologies address patients with complaints of tinnitus who fall into two categories encountered in clinical practice. One is the patient who has had hearing loss for years and yet awakens suddenly with tinnitus. The other is the rare patient who has normal hearing, even in the ultra-high frequencies, no other dietary or toxic risk factors, and no psychiatric comorbidities who complains of tinnitus. For these patients, careful history-taking may uncover a traumatic or emotional event that was coincident with the onset of their tinnitus. Similarities between tinnitus and phantom limb pain have fueled the hypothesis that both are "aversive memory networks." According to this theory, the phantom awareness (tinnitus) only becomes conscious when linked to other brain networks, and then becomes bothersome when linked by learned associations with unpleasant emotions (17).

Risk Factors

The most prevalent risk factor for subjective, nonpulsatile tinnitus is hearing loss. As discussed above, hearing loss may be the initial instigating factor underlying nonpulsatile tinnitus. Frequently this hearing loss includes significant sensorineural losses at higher frequencies; occasionally, the hearing loss can only be detected using a high-frequency audiogram (Fig. 161.2). Of note, not every patient with hearing loss will have complaints of tinnitus,

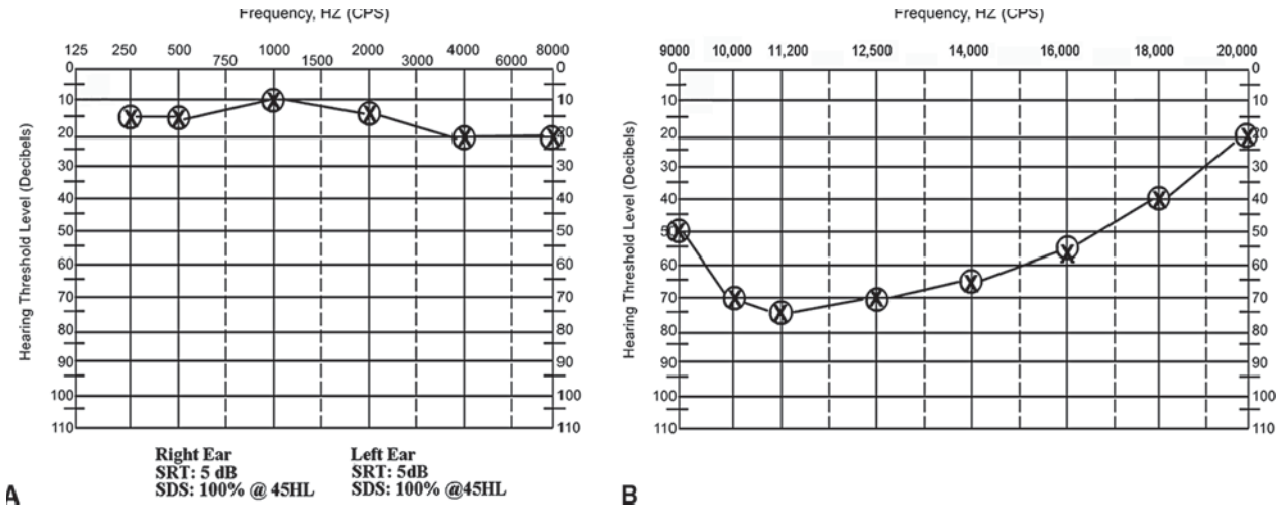

Figure 161.2 Normal **(A)** and high-frequency **(B)** audiograms of a patient with nonpulsatile tinnitus, demonstrating normal hearing from 250 to 8,000 Hz and a very-high-frequency bilateral hearing loss.

and in fact, at least 27% of patients with profound sensorineural hearing loss (SNHL) will not have tinnitus (18). Meniere's disease is associated with nonpulsatile tinnitus that typically worsens during acute vertiginous episodes. Conductive or mixed hearing loss can also be associated with tinnitus, including that caused by otosclerosis, ossicular discontinuities, or obstruction of the external auditory canal by cerumen or other factors.

Other risk factors for nonpulsatile tinnitus include intake of certain dietary, medicinal, and illicit substances. For instance, caffeine, aspirin, ibuprofen, and nicotine can cause tinnitus or exacerbate preexisting tinnitus. Even if the individual patient has used these substances previously, changes in intake patterns due to shift work, injury, or changes in metabolism due to aging can lead to worsened tinnitus.

Hyperacusis

Hyperacusis, or increased sensitivity to sound, is often seen in the context of tinnitus. Patients will complain of discomfort or pain in the presence of sounds that are typically tolerated by normal people, including car horns, sounds associated with cooking, and even loud conversations. Sometimes this sound intolerance will be limited to certain frequencies. As the patient continues to experience hyperacusis, the threshold of sound intensity required to cause discomfort may decrease. In severe cases, patients may significantly alter their behavior (wear ear muffs in public, avoid going outdoors) in order to avoid the discomfort and pain caused by exposure to these sounds. Often, hyperacusis is associated with hearing loss (19).

For patients with hearing loss, intolerance to loud sounds may result from overrepresentation of the sound frequencies bordering a hearing loss in the central auditory system (recruitment). Exposure to these sound frequencies causes intolerable overstimulation of the auditory cortex due to recruitment. A second possibility is that hyperacusis results from selective loss of efferent input to the inner ear. These efferents are critical in regulating basilar membrane excursion and firing of afferent eighth nerve fibers in response to a sound stimulus (20).

Patients may develop hyperacusis following a single exposure to a sudden loud noise (e.g., gunshot, car airbag deployment) in the absence of a detectable hearing loss. Other potential etiologies for hyperacusis in the absence of hearing loss include head trauma, migraine, depression, Bell's palsy, Ramsay Hunt Syndrome, Lyme disease, Addison's disease, and following stapes surgery (19,20). Hyperacusis is seen in over 80% of patients with Williams syndrome, a genetic disorder characterized by craniofacial and dental anomalies, mental retardation, hypertension, cardiovascular disease, and perfect pitch (21,22).

Mild hyperacusis can be managed by avoidance of sounds that stimulate an unpleasant reaction (19). Thus for hearing aid users with hyperacusis, the maximum comfort level should be utilized in programming their aids. Further treatment is required for patients with severe hyperacusis that affects their activities of daily living. For these patients, tinnitus retraining therapy (TRT) can be extremely effective in increasing their tolerance to everyday sounds (23).

Diagnostic Evaluation

Patients with nonpulsatile, subjective tinnitus should always have a standard, complete audiogram performed as the initial step in their evaluation, as discussed above. For patients with complaints of bilateral tinnitus who have a normal standard audiogram (up to and including 8,000 Hz pure tone thresholds), a high-frequency audiogram may be useful in determining the etiology of tinnitus, particularly in patients with no other risk factors.

Magnetic resonance imaging (MRI) of the brain and brainstem with gadolinium is a requisite test for patients with unilateral tinnitus (Fig. 161.3). Even in the presence of

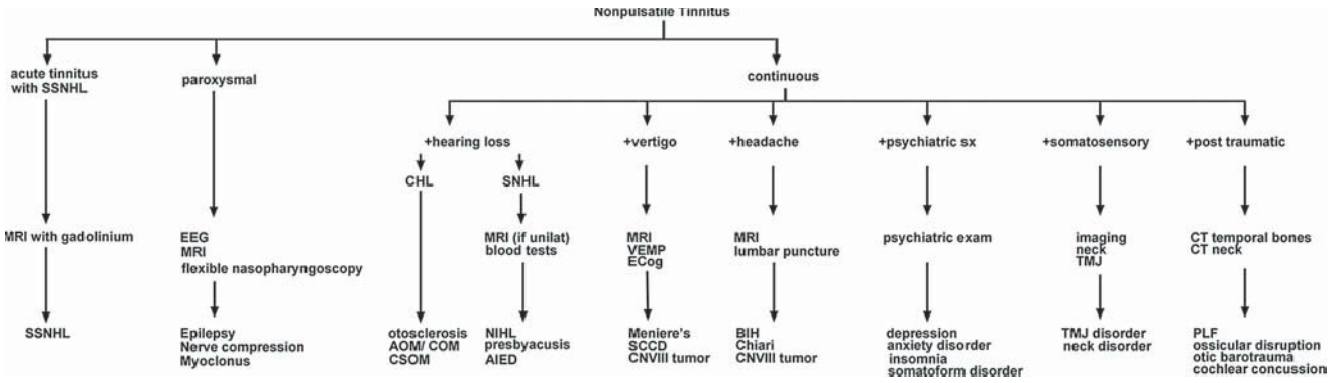

Figure 161.3 Algorithm for evaluation of nonpulsatile tinnitus. Modified from the Tinnitus Research Initiative diagnosis and treatment of tinnitus (24). AIED, autoimmune inner ear disease; AOM, acute otitis media; BIH, benign intracranial hypertension; CHL, conductive hearing loss; CN cranial nerve; COM, chronic otitis media; CSOM, chronic serous otitis media; CT, computed tomography; ECog, electrocochleography; EEG, electroencephalogram; VEMP, vestibular evoked myogenic potential; MRI, magnetic resonance image; PLF, perilymphatic fistula; SCCD, semicircular canal dehiscence; SSNHL, sudden sensorineural hearing loss; sx, symptoms; TMJ, temporomandibular joint; unilat, unilateral; NIHL, noise-induced hearing loss.

normal or symmetrical hearing, patients with unilateral tinnitus may have a vestibular schwannoma or other intracranial anomaly requiring further treatment (25) (Fig. 161.1). The complete evaluation of patients with symptoms consistent with Meniere's disease also should include an MRI.

Treatment

Occasionally, treatment of an underlying pathology causing hearing loss will alleviate nonpulsatile tinnitus. For instance, removal of cerumen or a foreign body may alleviate both the hearing loss and tinnitus associated with occlusion of the external auditory canal. Stapedectomy for a patient with otosclerosis in the absence of a significant sensorineural loss may alleviate his or her tinnitus. Decreased caffeine or aspirin intake may substantially improve or alleviate tinnitus in patients ingesting high levels of these substances.

These rapid cures are not possible for the majority of patients presenting with the primary complaint of nonpulsatile tinnitus. Management options for these patients include hearing aids, tinnitus maskers, TRT, biofeedback, electrical or magnetic stimulation, pharmacotherapy, and cochlear implantation.

Amplification

The majority of patients with subjective tinnitus have a significant hearing loss. Use of a well-fitted hearing aid can improve subjective tinnitus in 50% of patients with hearing loss and tinnitus. Hearing aids increase the ambient noise perceived by the patient, thus masking the tinnitus (26). Additionally, restoration of auditory input within the lost frequencies, particularly those matching the frequency spectrum of the tinnitus, lead to central auditory plasticity, which can decrease tinnitus. Ideally, patients with bilateral subjective tinnitus should be fitted with bilateral hearing aids that include a wide, high-frequency amplification band and open ear mold. The open mold will decrease the occlusion effect, and extend amplification at higher frequencies. Ideal hearing aid settings for a patient with hearing loss and tinnitus would include an omnidirectional microphone, a lower compression point, disabled digital noise reduction, and active digital feedback cancellation (26).

Tinnitus Masking

Nonpulsatile and pulsatile tinnitus sounds can sometimes be covered (or masked) by external sounds, thus blocking the tinnitus percept and the unpleasant sensations associated with these sounds. To use this therapy effectively, the physician or therapist needs to exclude patients for whom the tinnitus cannot be masked, the masking sound is perceived as worse than the tinnitus sound, or the tinnitus sound is tolerable as it is (27,28). For many patients, use of environmental sounds such as a noise generator or radio can effectively and inexpensively mask their tinnitus. However, in certain situations, use of such environmental sounds may not be appropriate. Use of an ear-level tinnitus masker, a small device that makes a sound matched to the tinnitus sound the patient perceives, yields total relief for 6% of patients and partial relief for 23% to 64% of patients (27,29). The addition of masking tones to amplifications from a hearing aid can mask tinnitus sounds more effectively than a hearing aid alone (30).

For most patients, masking sounds include many of the frequencies of their hearing loss (29). Occasionally, use of masking sounds can lead to residual inhibition, or cessation of the tinnitus sound, for a period of seconds to hours (29). Residual inhibition is hypothesized to result from inhibition of synchronous activity within the auditory pathway from masking sounds that lie within the frequencies affected by hearing loss being presented above the minimal masking threshold (29). Some proponents of other therapies for tinnitus, particularly TRT, feel that tinnitus maskers may prevent habituation to the tinnitus perception and can therefore impede these patients' ultimate recovery (31). Certainly, those who benefit from tinnitus maskers require ongoing use of the masker to manage their tinnitus, especially if this is their sole treatment strategy (27,29).

Tinnitus Retraining Therapy

TRT is an effective management strategy for both subjective tinnitus and hyperacusis. TRT is based on the concept that habituation to the unpleasant stimulus can minimize the reactions that these patients experience (Fig. 161.4). Up to 80% of patients experience tinnitus without a significant unpleasant association; and tinnitus severity is not equal to the intensity of the perceived stimulus. For patients with complaints of significant tinnitus, Jastreboff hypothesized that an initial link is made between the tinnitus percept and unpleasant limbic and autonomic reactions that lead to an unconscious linkage between the tinnitus sound and the reaction (31). Since habituation to unpleasant stimuli

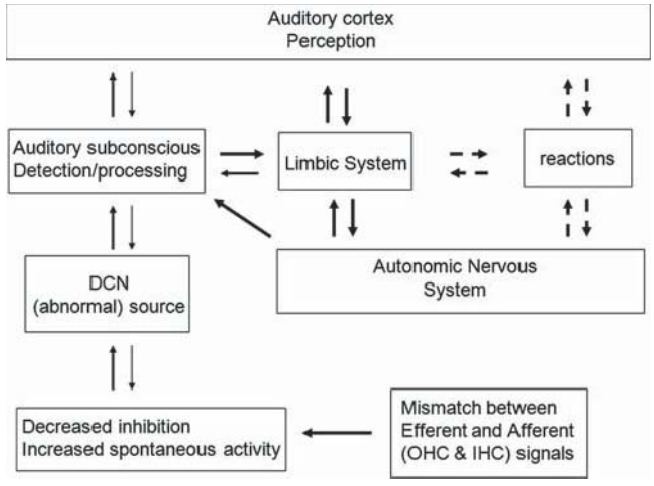

Figure 161.4 Hypothesized neural network underlying tinnitus generation according to Jastreboff (30). This pathway forms the theoretical foundation for TRT.

occurs all the time, Jastreboff surmised that habituation to tinnitus perceptions can occur as well (Fig. 161.4). Unlike other therapies for tinnitus, TRT does not seek to reduce production of the tinnitus sound but instead attempts to change the linkage between the tinnitus perception and autonomic and limbic systems using extensive counseling and sound therapy. Counseling attempts to reclassify tinnitus as a neutral stimulus and is felt to be necessary to allow habituation. Sound therapy decreases abnormal neural activity causing tinnitus and can also be an effective means to decrease hyperacusis via exposure and habituation. Studies have shown that completion of a 12-month course of TRT can decrease scores on the Tinnitus Handicap Index, a validated scale of tinnitus severity, by up to 80% (reviewed in [31]).

Neuromonics

Based on success with tinnitus maskers and counseling, investigators sought to incorporate both phenomena into treatment for tinnitus. The Neuromonics device uses sound therapy, extensive tinnitus education, and cognitive therapy to treat patients with tinnitus. Patients begin their therapy by listening to preprocessed mixed "calming music" (a combination of baroque and new age) combined with noise mixed by proprietary algorithm for 2 to 4 hours daily. The sound spectrum of this noise is shaped according to patient's audiogram to compensate for hearing loss. Over 6 to 24 months, the noise sounds are gradually decreased. The underlying rationale is that initial wide frequency stimulation will counter the auditory deprivation resulting from preexisting hearing loss, pleasant and calming sounds counter negative feedback from the limbic system, and matched tinnitus tones also incorporated into the program will lead to gradual desensitization (32). Following completion of therapy, up to 77% of patients report improvement of their tinnitus (33).

Cochlear Implantation

Up to 80% of cochlear implant recipients have moderate to severe tinnitus. All studies examining tinnitus in cochlear implant recipients show an improvement following unilateral multichannel implantation in most implantees (60% to 90%), with some recipients exhibiting improvement of contralateral tinnitus through residual inhibition (34–38). Some patients, however, experience new onset or increased severity of their tinnitus following cochlear implantation (34,35,39). Worsening of preexisting tinnitus and development of new-onset tinnitus is more common in the setting of bilateral cochlear implantation (40).

Pharmacotherapy

A wide variety of standard medications and herbal supplements have been used by patients to reduce or alleviate their tinnitus, including anesthetic agents (IV lidocaine), anticonvulsants, antidepressants, antihistamines, benzodiazepines, diuretic, GABA agonists (Baclofen), Ginko biloba extracts, histamine, steroids, and vitamins. Of these, only a few agents have been shown to be effective agents at consistently improving patients' perceptions of their tinnitus: IV lidocaine, antidepressants, and steroids.

Lidocaine, an amine-type local anesthetic and class 1B antiarrthymic drug, blocks voltage gated sodium channels and has effects on the firing of a number of other neuronal channels. Lidocaine suppresses tinnitus in 40% to 80% of patients. Sites of action are located in both the cochlea and CNS. Intravenous lidocaine may be effective up to 4 weeks following injection, despite an elimination half-time of 90 to 120 minutes in most patients (41). Intratympanic injection of lidocaine is also effective for treatment of tinnitus, but the high incidence of vestibular side effects limit its use (42).

Antidepressants have been tested in a number of trials for the treatment of nonpulsatile tinnitus, including at least five double-blind placebo controlled studies (42,43). These studies are characterized by varying entry criteria, including the duration and severity of tinnitus, drug used, duration of its use, assessment of efficacy, and presence or absence of depression in trial participants. Often these trials were not assessed on an intention to treat basis. Drugs studied include nortriptyline, paroxetine, sertraline, and trimipramine. Overall, however, patients with anxiety, depression, and more severe tinnitus are more likely to benefit from use of these medications (42,44).

Steroids, either intratympanic or orally administered, have been described as an effective method of control of tinnitus for patients with Meniere's disease (42). However, the majority of trials of steroid therapy for Meniere's disease utilized control of vertigo as their primary outcome measure. In these trials, control of tinnitus was a secondary or tertiary outcome measure. Intratympanic steroids were shown to be ineffective for treatment of subjective tinnitus in a randomized control trial of 70 patients (45).

A number of dietary supplements and vitamins have been used to treat tinnitus, including multivitamins (A, B1, B3, B6, B9, C, E, magnesium, manganese, selenium, and zinc), antioxidants (flavonoids, Coenzyme Q, carotenoids) and herbal remedies (ginko biloba, cimicifuga racemosa, cornus officinalis, verbascum desiflorum, yoku-kan-san). Although typically considered harmless, these supplements may have significant side effects and may interact with prescription medications. Typically, there is little evidence of efficacy, and often they can be costly (42).

Microvascular Decompression

Vascular compression of the vestibulocochlear nerve (CN VIII) as a cause of nonpulsatile or pulsatile tinnitus is highly controversial. In 1975, Jannetta proposed that tinnitus, vertigo, and SNHL could be attributed to vascular compression of CN VIII from redundant loops of the anterior inferior cerebellar artery in the cerebellopontine angle (46). Recent MRI studies documenting frequent, asymptomatic contact between a vascular loop and

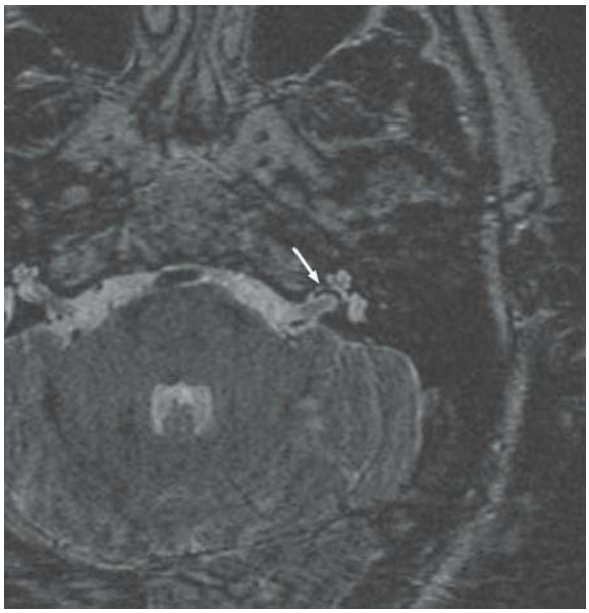

Figure 161.5 Axial MRI using CISS demonstrates a left-sided vascular loop within the IAC (*white arrow*).

CN VIII dispute the existence of this syndrome and caution against microvascular decompression surgery (47). Nevertheless, reports of efficacious microvascular decompression of the vestibulocochlear nerve suggest surgical treatment of vascular loop syndrome may be useful for some patients (48,49). Vascular loops are best identified on MRI using constructive interference in the steady state (CISS) sequences (Fig. 161.5).

Other Therapies

A variety of other therapies have been successfully used for the treatment of nonpulsatile tinnitus in studies of small groups of patients. Neurofeedback strategies can decrease perception of tinnitus sounds in patients who are able to modulate their brain activity patterns (50). Both repetitive transcranial magnetic stimulation and transcranial direct current stimulation have been demonstrated to decrease perceived tinnitus intensity in study participants in double blind placebo control studies (51,52).

PULSATILE TINNITUS

Etiology

There are numerous causes of pulsatile tinnitus. Arterial and venous etiologies are by far the most common. Vascular tumors of the temporal bone, such as tympanic and jugular paragangliomas, vascular malformations, dehiscent jugular bulb, jugular diverticula, and vascular loops of the internal auditory canal (IAC) can present with unilateral pulsatile tinnitus. Nonvascular etiologies include palatal or middle ear myoclonus, dehiscent semicircular canal (superior, lateral, or posterior), benign intracranial hypertension, otosclerosis, middle ear effusion or ossicular abnormalities, temporomandibular joint dysfunction, and patulous ET (Table 161.3). However, for a substantial percentage of patients with pulsatile tinnitus, a definite etiology cannot be identified despite thorough evaluation. Following a brief section on diagnostic evaluation, we discuss individual etiologies of pulsatile tinnitus and their corresponding treatment options.

TABLE 161.3 ETIOLOGIES OF PULSATILE TINNITUS

Vascular		**Developmental**	ETD
Venous	Jugular bulb anomalies		Paget disease
	Idiopathic intracranial HTN		Otitis media
	Dural venous sinus aneurysm	**Infectious**	Serous otitis media

Arterial	Atherosclerosis	**Misc.**	SSC dehiscence
	Dural AVM		Otosclerosis
	Carotid artery anomalies		Palatal/M.E. myoclonus
	Vascular compression		
	Aneurysm		
	Hyperdynamic flow state		

AVM, arteriovenous malformations; ETD, Eustachian tube dysfunction; HTN, hypertension; ME, middle ear; SSC, semicircular canal.

DIAGNOSTIC EVALUATION

Patients with complaints of tinnitus should have a behavioral audiogram including air and bone conduction with appropriate masking, speech discrimination testing, immittance testing including tympanograms and acoustic reflex testing. VEMP should be considered when a semicircular canal dehiscence (SCD) is suspected. VNG- or electronystagmography (ENG), and quantitative measurement of middle ear compliance should be employed in circumstances warranting these tests (53).

A variety of imaging techniques, including carotid Doppler ultrasonography or duplex scan, computed tomography (CT), CT angiography (CTA), MRI, MR angiography (MRA), MR venography (MRV), and the use of four-vessel angiography, have a role in the evaluation of pulsatile tinnitus. Despite combined testing with a variety of these imaging modalities, definitive diagnosis of the etiology underlying pulsatile tinnitus is possible in only 68% to 72% of patients (4,54,55).

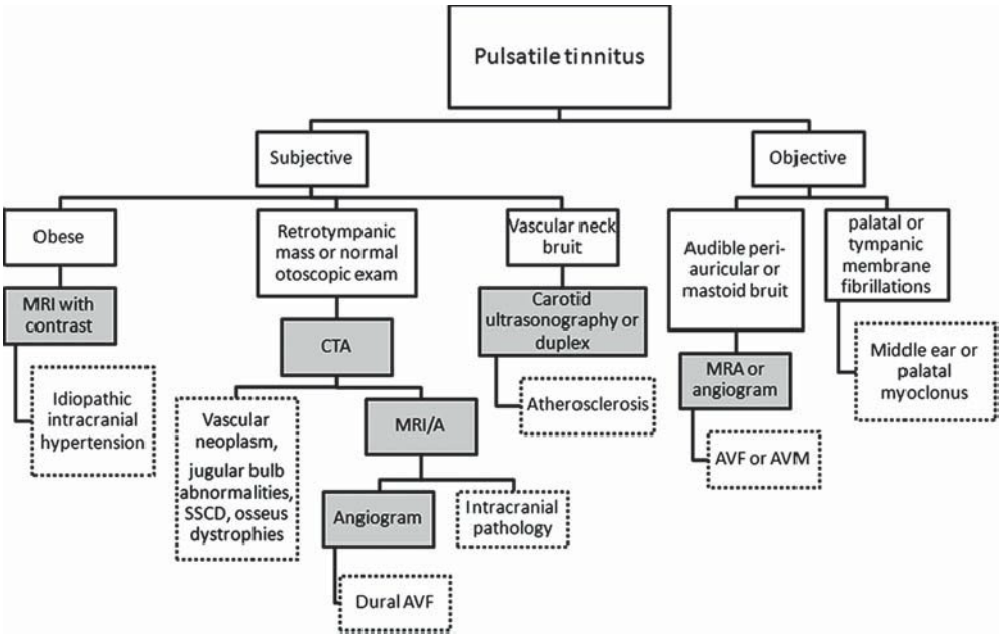

Figure 161.6 Algorithm for evaluation of pulsatile tinnitus. Modified from Mattox (4). AVF, arteriovenous fistula; AVM, arteriovenous malformation; CTA, computed tomography angiography; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging.

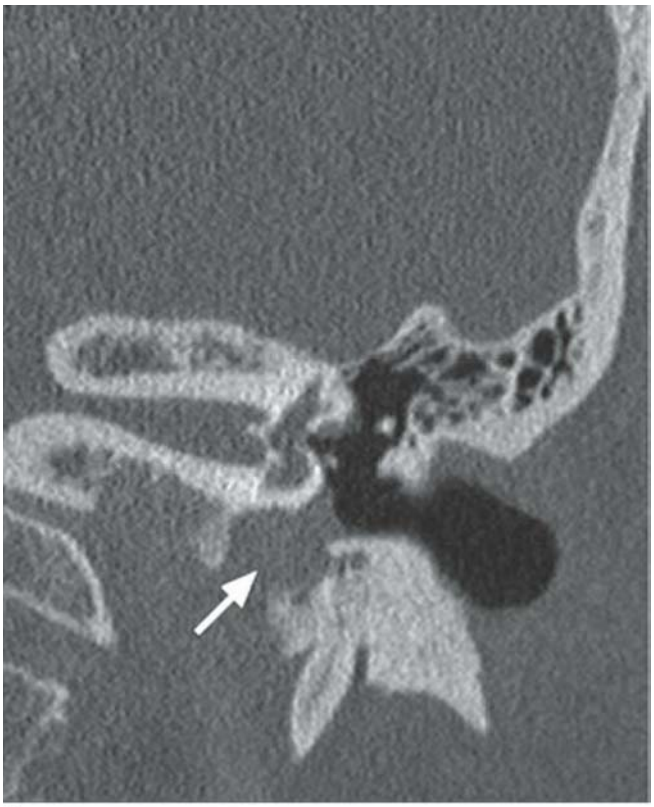
Many algorithms have been formulated to guide use of radiologic testing. Mattox and Hudgins (4) (2008) proposed an algorithm based on patient symptoms and physical exam findings (Fig. 161.6). Patients with a visible vascular mass on otoscopic microscopy or a family history of paraganglioma should undergo CT of the temporal bone with intravenous contrast (Fig. 161.7). Patients with a normal middle ear exam and an audible vascular neck bruit should first undergo carotid Doppler ultrasonography or a CTA of the neck to assess for carotid atherosclerotic disease. Patients with suspected arterial vascular disease should still be evaluated with radiologic imaging despite a negative neck exam, because hemodynamically significant stenoses may be present without audible vascular bruits (4). Initial evaluation with CTA of the neck and temporal bones is also appropriate in patients whose tinnitus is modified by moderate neck compression suggesting a venous etiology. CTA allows evaluation of both arterial and venous vasculature as well as the fine bony structure of the temporal bone, allowing diagnosis of anatomic abnormalities such as dehiscent jugular bulb in addition to vascular etiologies. Patients presenting with symptoms of pulsatile tinnitus and autophony suggesting a diagnosis of SCD or patulous ET should be evaluated with high resolution, noncontrast CT of the temporal bone with images reformatted in coronal and Poschel's and Stenver's views (56) (Fig. 161.8). Primary use of MRA/MRV in the evaluation of patients with pulsatile tinnitus has fallen from favor as both the vascular and bony anatomy of the temporal bone is superior with CT angiography, although these tests still have a role in the evaluation of patients who are unable to receive or refuse iodinated contrast (4,57). Because CTA is unable to identify small dural arteriovenous malformations (AVMs), negative CTA studies may be followed by four-vessel angiography (4,54,55). Use of four-vessel angiography does not guarantee diagnosis, however, and should be used judiciously due to the risks of the procedure. In a study of 54 patients with pulsatile tinnitus, 44 were definitively diagnosed on CTA. Out of the 10 patients with negative CTAs, the four-vessel angiogram identified the definitive diagnosis (carotid dissection) in only 1 patient. In obese patients presenting with pulsatile tinnitus, some authors advocate for MRI as the initial imaging study to assess for presence of benign intracranial hypertension (pseudotumor cerebri) (4).

Vascular Anomalies

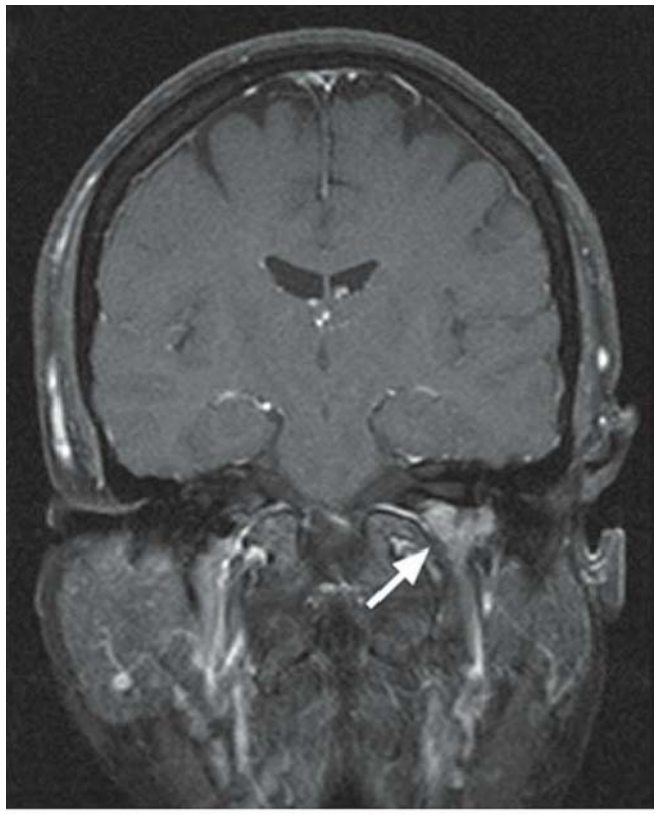
Abnormalities of the intracranial venous system are the most common radiologic finding in patients with pulsatile tinnitus and a normal middle ear exam. The most commonly reported anomalies are high or dehiscent jugular bulbs and sigmoid sinus diverticula (Fig. 161.9). Cervical atherosclerotic disease is the most common arterial etiology of pulsatile tinnitus (4,5,54,55).

Anomalies of the Jugular Bulb

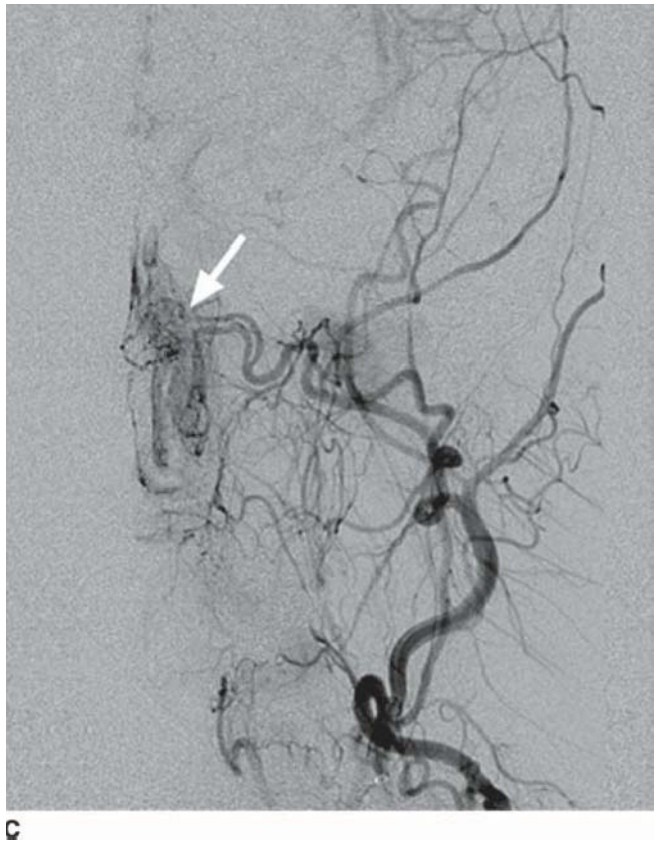
Jugular bulb anomalies, including dehiscent high-riding jugular bulbs and jugular bulb diverticula, are frequently associated with tinnitus of venous origin (Fig. 161.9). Anatomically, the jugular bulb represents the junction between the proximal internal jugular vein and the sigmoid sinus at the skull base. High-riding jugular bulbs



A



B



C

Figure 161.7 Left-sided glomus jugulare (*white arrows*) demonstrated by coronal reformatted CT **(A)**, coronal contrast-enhanced MRI **(B)**, and external carotid angiography **(C)**.

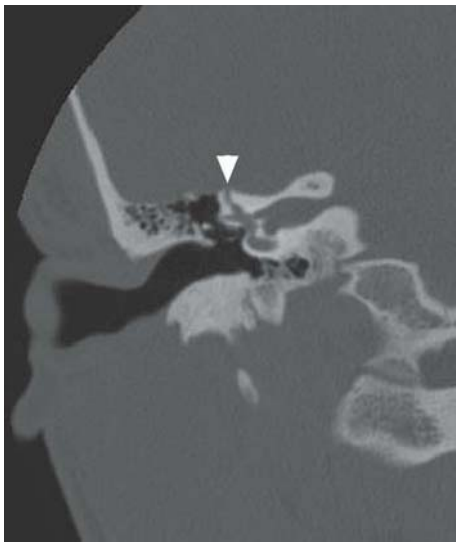


Figure 161.8 Coronal reformatted CT shows right superior SCD (*white arrowhead*).

are defined as extending above the tympanic annulus or rising to within 2 mm of the floor of the IAC (58,59). Jugular bulb diverticula represent an outpouching of the vessel wall into the middle ear, mastoid, or petrous apex. Estimates of the incidence of jugular bulb anomalies range from 4% to 20% (59,60). These anomalies may be acquired rather than congenital, as the jugular bulb does not develop until after 2 years of age. While the exact pathogenesis remains unknown, development of jugular bulb anomalies appear to be related to venous blood flow dynamics (58).

In some cases, a smooth, convex, blue mass can be visualized on otoscopy. Tinnitus of venous origin often worsens with Valsalva and decreases with compression of the ipsilateral internal jugular vein in the neck. Abnormalities of the jugular bulb are best visualized on high-resolution bone algorithm CT scans of the temporal bone (4,54,59,61) (Fig. 161.9).

Management options for symptomatic jugular bulb anomalies range from observation to surgical or endovascular intervention. Published reports describe successful improvement or elimination of pulsatile tinnitus with middle ear floor reconstruction, jugular vein ligation, and endovascular coil embolization; however, significant side effects associated with these interventions (notably benign intracranial hypertension) have limited their widespread application (60,62–64).

Sigmoid Sinus Diverticulum

Sigmoid sinus diverticula account for approximately 20% of cases of pulsatile tinnitus originating from a venous source (4,65). While the exact pathophysiology and pathogenesis remain unknown, it is hypothesized that turbulent blood within the sigmoid sinus may lead to erosion of the overlying mastoid bone with development of a venous diverticulum. As with other abnormalities of the jugular bulb, diverticula of the sigmoid sinus are best visualized on CT or CTA/Venography. Successful elimination of pulsatile symptoms has been reported with transmastoid reconstruction of the sigmoid wall and with endovascular coil embolization and stenting. In these cases, obliteration of the diverticulum was accomplished without thrombosis or occlusion of the sigmoid sinus lumen (65–67).

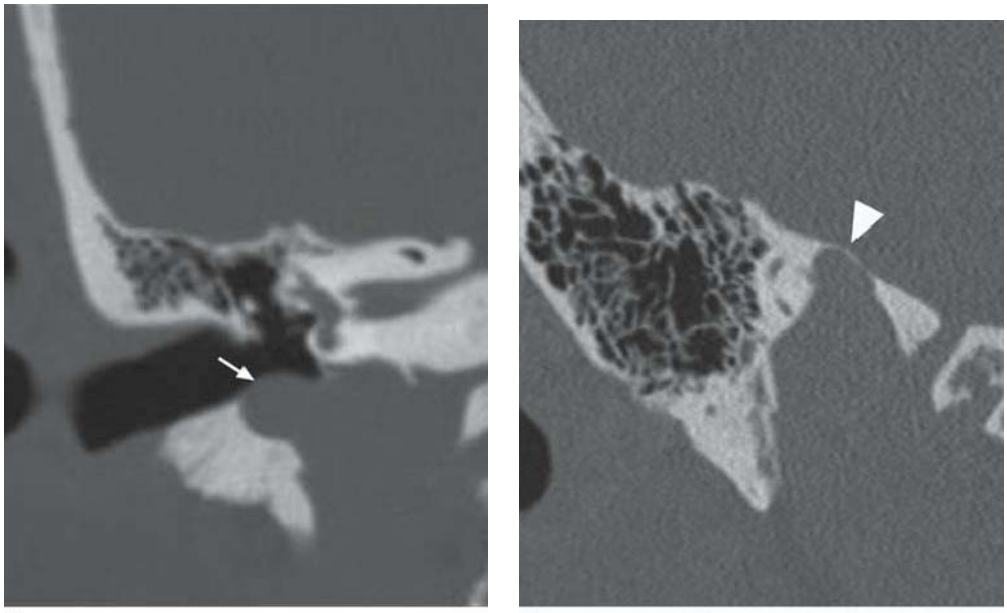

Figure 161.9 Jugular bulb anomalies associated with pulsatile tinnitus, as demonstrated on coronal CT of the temporal bones. Dehiscent jugular bulb (*white arrow*) **(A)** and a diverticulum (*white arrow head*) of the jugular bulb **(B)** from two different patients.

Dural Arteriovenous Malformation/Fistula

Dural arteriovenous fistulae (AVF) or AVMs are the most common cause of objective pulsatile tinnitus in the setting of a normal otoscopic exam (54,61,68) (Fig. 161.10). Dural AVM/F constitute 10% to 15% of all intracranial vascular malformations and typically occur along the intracranial venous sinuses, most often the transverse and sigmoid sinuses (68). AVM/F may be congenital or acquired, with symptoms precipitated by trauma, infection, puberty, or pregnancy (69). Depending on the location, size, and drainage pattern, patients may be clinically asymptomatic or present with pulsatile tinnitus, headache, neurologic compromise, or intracranial hemorrhage (68). These abnormal connections between dural arteries and venous sinuses may not be readily detectable. CT or MRI imaging and four-vessel angiography is often required for diagnosis (4,54,70). Management decisions are multifactorial and must incorporate the severity of the presenting symptoms, anatomic characteristics of the lesion, and the patient's age and comorbidities. Treatment modalities include endovascular embolization, surgical excision of the fistula and gamma knife radiosurgery (68,69,71–73).

Atherosclerotic Carotid Artery Disease

Many patients with tinnitus have at least one risk factor for atherosclerosis. Pulsatile tinnitus may be the first manifestation of atherosclerotic carotid artery disease (61,74,75). Tinnitus may result from impairment of the inner ear microcirculation due to atherosclerotic disease or from the referred sound of turbulent flow through sclerotic carotid arteries. Physical exam of a patient with tinnitus should always include bilateral auscultation of the neck; however, not all hemodynamically significant stenoses lead to audible bruits. A variety of imaging modalities can identify clinically significant atherosclerotic disease. Specifically, atherosclerotic plaques can be seen on ultrasonography, duplex scan, contrast-enhanced CT, CTA, MRI, and MRA; duplex scan also allows visualization of turbulent flow and increased thickness of the carotid wall (61,75,76). Symptoms of pulsatile tinnitus resulting from significant carotid stenoses typically resolve following carotid endarterectomy or intravascular stenting (77,78). Intravascular turbulence due to a torturous carotid artery may also yield a bruit. Distinction between this benign entity and significant carotid stenosis should be made with duplex scan, potentially followed by CTA or MRA as necessary.

Figure 161.10 Common carotid angiogram in lateral projection demonstrates a dural arteriovenous fistula (*arrow*).

Congenital Carotid Anomalies

Congenital anomalies of the intratemporal carotid artery, specifically an aberrant carotid artery or a persistent stapedial artery, may result in pulsatile tinnitus. In rare cases, the intrapetrous carotid artery is replaced by an enlarged inferior tympanic artery (a branch of the ascending pharyngeal). Rather than entering the skull base through the inferior tympanic canaliculus, the inferior tympanic artery anastomoses with the caroticotympanic artery in the middle ear where it is visible as a pulsating, erythematous mass. The aberrant carotid then resumes its course through the intrapetrous carotid canal. A dehiscent anatomically normal carotid artery may also present with pulsatile tinnitus and a pulsating middle ear mass (61).

Persistence of the normal fetal stapedial artery can occur in the presence of a normal or aberrant carotid artery. The stapedial artery crosses the stapes footplate through the obturator foramen, passes across the cochlear promontory and exits the middle ear adjacent to the geniculate ganglion. In the presence of a persistent stapedial artery, neither the middle meningeal artery nor the foramen spinosum develop, as stapedial arteries supply the territory of the middle meningeal artery. While the caliber of the stapedial artery is typically too small for resolution on MRI, thin cut CT allows identification of the middle ear mass, enlargement of the geniculate facial canal and absence of the foramen spinosum (61,76,79). Ligation, either via direct surgical obliteration or embolization, must be preceded by angiography to delineate any intracranial territory supplied by the persistent stapedial artery and ensure there is redundant blood supply to that region. Due to the potentially devastating consequences of intracranial ischemia and bleeding, treatment is rarely pursued (80).

Other Vascular Abnormalities and Malformations

Carotid-cavernous fistulas (CCF) can be high-flow, direct communications between the internal carotid artery and the cavernous sinus or low flow dural-based fistulae, the latter of which are minimally symptomatic. Direct CCFs classically present with chemosis, proptosis, ophthalmoplegia, and diplopia. Low-flow dural CCFs manifest with headache, isolated cranial nerve palsies and pulsatile tinnitus (81). Sudden onset of pulsatile tinnitus has also been

reported with direct CCFs, most commonly as the primary presenting symptoms of spontaneous or posttraumatic CCFs (81,82).

Intracranial and extracranial aneurysms, including dilation of the intratemporal petrous carotid, vertebral artery and basilar artery in the cerebellopontine angle cistern, may present with pulsatile tinnitus. Spontaneous dissection of the internal carotid artery can also present with pulsatile tinnitus, as well as the more common symptoms of pain, cerebral ischemia, Horner's syndrome and intracranial hemorrhage (Fig. 161.11). Although fibromuscular dysplasia of the internal carotid artery most commonly presents with cerebral ischemia, it may also manifest as pulsatile tinnitus (83). These vascular abnormalities are best diagnosed with MRA or CTA. Vascular anomalies may require urgent or emergent management depending on the severity of symptoms at presentation. Acute interventions are aimed at reducing intracerebral ischemia and restoring arterial blood flood. Treatment options range from conservative management with anticoagulation and/or antiplatelet therapy to operative intervention (endovascular [intraluminal dilation or stenting] or surgical resection–anastomosis, endarterectomy or vessel reconstruction) (84–86).

Other vascular anomalies and atypical flow states can cause pulsatile tinnitus. Venous anatomic abnormalities have also been associated with pulsatile tinnitus including dural venous sinus aneurysm, dilated mastoid or condylar emissary veins, and stenosis of the dural sinuses, specifically of the transverse or sigmoid sinuses (87,88). Hyperdynamic states leading to increased cardiac output can cause pulsatile tinnitus. These states include anemia, thyrotoxicosis, and pregnancy. Treatment of the underlying pathology and decrease in cardiac output will typically cure the tinnitus (5).

Figure 161.11 CT angiogram of the skull base shows a small, irregular left internal carotid artery (*arrowhead*) indicating internal carotid artery dissection.

Vascular Neoplasms

Paragangliomas

Paragangliomas, or glomus tumors, are the most common vascular tumor of the temporal bone. Believed to arise from paraganglia on the cochlear promontory surrounding Jacobson's nerve (glomus tympanicum) or from the adventitia of the jugular bulb within the jugular foramen (glomus jugulare), these highly vascularized tumors typically present with pulsatile tinnitus (89,90). On otomicroscopy, a reddish, pulsatile mass is visualized medial to the tympanic membrane. Histologically, paragangliomas are composed of chief cells and supporting sustentacular cells surrounded by rich capillary network. Chief cells are neuroendocrine-derived chemoreceptor cells that contain neurosecretory granules capable of clinically significant catecholamine secretion, although this is rare (1% to 2% of patients) (91). Although histologically benign, rare malignant forms have been characterized by the presence of nodal or distant metastases (91). The vascular supply to paragangliomas of the temporal bone commonly originates from the external carotid system, specifically the ascending pharyngeal and occipital arteries, although it can also arise from the internal carotid (caroticotympanic branches of the intrapetrous carotid) or the vertebrobasilar system (posterior–inferior cerebellar artery).

Approximately 80% of paragangliomas are sporadic. The remainder are inherited in an autosomal dominant fashion, sometimes with maternal imprinting, are more likely to be multifocal, and present at an earlier age (91–93). A number of mutations in subunits of mitochondrial succinate dehydrogenase (SDHB, SDHC, and SDHD), which plays a critical role in the mitochondrial electron transport chain, have been identified in these families (94,95). Genetic testing is now available to identify the presence of these mutations in patients at high risk for familial inherited paraganglioma (91).

A variety of staging systems are currently employed for characterization of temporal bone paragangliomas, including those ascribed to Fisch, Glasscock-Jackson, and de la Cruz. Each attempts to characterize the tumor's locoregional extent by assessing its relationship to surrounding neurovascular, intracranial, and temporal bone structures (96–98). The size and extent of tumor can be staged based on radiologic imaging. Debate exists regarding the most appropriate initial imaging modality, although both CT and MRI are typically employed in diagnosis (Fig. 161.7). Erosion of the jugular foramen is best visualized on high-resolution CT (HRCT) of the temporal bone. Compared with CT, MRI is superior in evaluating tumor vascularity as paragangliomas enhance intensely with gadolinium.

On MRI, flow voids within the tumors are characterized by their "salt and pepper" appearance, although this feature can be missing in smaller paragangliomas (61). Additionally, MRI provides better evaluation of tumor extension and multicentricity (99). MRA can be used preoperatively to identify tumor vascular supply, while MRV can evaluate the patency of the jugular bulb, jugular vein, sigmoid and transverse sinuses. Sensitivity and specificity between MRA and standard four-vessel digital subtraction angiography are comparable at 90% and 92% respectively (99). Unlike four-vessel angiography, however, MRA does not afford the opportunity for preoperative tumor embolization.

Treatment options for temporal bone paragangliomas include observation, radiation therapy, and surgery. Currently, management decisions are based on a variety of factors, including tumor size and location, as well as patient age, comorbid conditions and preference. Surgical control rates average 80% to 95% (90,100–103). While surgical excision of glomus tympanicum tumors can be accomplished with little morbidity, removal of a glomus jugulare can risk function of CN VII, IX, X, and XI. Postoperative dysfunction of the lower cranial nerves within the jugular foramen as well as the facial nerve and sequelae resulting from ligation of the jugular vein may be significant. Both standard fractionated radiotherapy and gamma knife stereotactic radiation have been employed as primary treatment as well as adjuvant therapy following subtotal surgical resection or recurrence of glomus jugulare (101,102). Although associated with inhibition of tumor growth in greater than 90% of patients, radiation therapy is not always associated with a reduction in preoperative symptoms when used as a single modality (104–106).

Hemangiomas

Temporal bone hemangiomas, including facial nerve and cavernous hemangiomas, are rare vascular tumors of the temporal bone that can occasionally be associated with pulsatile tinnitus. Facial nerve hemangiomas are most commonly located at the geniculate ganglion, but can also be localized to the IAC. On imaging, facial hemangiomas are best diagnosed by their punctuate bone opacities and stippled appearance on bone algorithm CT scan. Cavernous hemangiomas are located predominately in the middle ear and can resemble a glomus tympanicum on both physical exam and radiologic imaging.

Nonvascular Etiologies

Idiopathic Intracranial Hypertension

Idiopathic intracranial hypertension (IIH), also known as benign intracranial hypertension or pseudotumor cerebri, is increased intracranial pressure (ICP) in the absence of obstructive hydrocephalus or other identifiable intracranial pathology and normal sized or small symmetric ventricles, normal cerebrospinal fluid (CSF) studies and CSF pressure greater than 200 mm H_2O. Most common in young, obese women, symptoms of IIH include headache, papilledema, and visual disturbances, pulsatile tinnitus, hearing loss, and vestibular abnormalities. These symptoms may present individually or in combination. The pathophysiology of pulsatile tinnitus in IIH is currently unknown. Potentially, increased ICP compresses the intracranial venous sinuses, creating turbulence in normally laminar blood flow that may lead to unilateral or bilateral pulsatile tinnitus (107). Alternatively, stretch or edema of the vestibulocochlear nerve (CN VIII) resulting from increased ICP may account for pulsatile tinnitus (107,108). Transmission of increased pressure to the perilymph through the cochlear aqueduct leading to increased stiffness of the basilar membrane has also been implicated in the pathophysiology of tinnitus in IIH (5,107). Treatment options for IIH include lifestyle modifications, particularly weight loss, as well as medical and surgical reduction of increased ICP. Acetazolamide, corticosteroids, and diuretics have been shown to improve tinnitus resulting from IIH (109). Surgical intervention can include CSF diversion procedures or bariatric surgery for weight loss. Both are effective in reducing ICP and improving tinnitus symptoms (109,110).

Semicircular Canal Dehiscence

Initially described by Lloyd Minor in 1998 for the superior semicircular canal, SCD syndrome results from a deficiency in the bony covering overlying one of the semicircular canals (111) (Fig. 161.8). Canal dehiscence syndrome is associated with a variety of auditory and vestibular manifestations, including sound or pressure-induced vertigo (111,112). Up to 50% of patients with superior SCD complain of pulsatile tinnitus; patients with posterior canal dehiscence resulting in contact between contents of the posterior canal and the jugular bulb or sigmoid sinus may also lead to pulsatile tinnitus (113,114). The diagnosis relies on history, HRCT imaging, preservation of the ipsilateral stapedial reflex, and a lower VEMP in the affected ear (112,115,116). Management options include observation or surgical correction of the dehiscence by plugging or resurfacing the dehiscence (116).

Palatal and Middle Ear Myoclonus

Pulsatile tinnitus can arise from palatal or middle ear myoclonus and may be either subjective or objective. Although both conditions are rare, palatal spasm is more common than middle ear myoclonus and has been reported in both adults and children (117–121). Muscle spasm of the levator veli palatini or tensor veli palatini cause ET opening leading to tinnitus, which can be subjective or objective. The etiology of palatal myoclonus is unknown, but has been hypothesized to localize to the upper brainstem in the Gillian-Mollaret triangle (120). Two forms have been described: symptomatic and essential. The former is marked by intrinsic brainstem or cerebellar disease while the latter (more common) form is characterized by the absence of

visible intracranial pathology on imaging (117,120). The diagnosis is made by visualization of a rhythmic tremor of the soft palate, which often requires flexible nasopharyngoscopy (119). Children with palatal myoclonus have a benign clinical course with frequent spontaneous resolution (117). Treatment options include observation, masking techniques, muscle relaxants, ET occlusion, and local injection of botulinum neurotoxin A (Botox) (120–124). Use of oral anticonvulsant therapy for these patients has generally been abandoned due to minimal efficacy and significant side effects (119,120,129).

Middle ear myoclonus can arise from spontaneous spasm of the tensor tympani or stapedius muscles. On examination, periodic movements of the tympanic membrane often can be visualized with otomicroscopy and may be recorded with immittance testing or tympanometry. Occasionally, these spasms can produce objective tinnitus. Although typically unilateral, bilateral myoclonus of the tensor tympani and stapedius muscles have been reported (125,126). Treatment options include observation, masking techniques, lysis of the stapedial or tensor tympani tendon, and use of Botox on pledgets placed into the middle ear (126–128). Stapedius myotomy has had similar success; however, common side effects include both hyperacusis and phonophobia (126,127,129).

Patulous Eustachian Tube

Pulsatile tinnitus arising from a patulous ET originates outside the auditory pathway. Normally closed in the resting position, a patulous ET leads to symptoms of autophony, aural fullness and, in some cases, pulsatile tinnitus. Patulous ET can result from weight loss following bariatric surgery or diuresis for treatment of congestive heart failure, pregnancy, hormonal therapy, nasopharyngeal scarring/ atrophy from radiation or surgery, rheumatologic disorders, allergic disease, and craniofacial abnormalities. Approximately one-third of cases are idiopathic (113,130,131). Diagnosis can be challenging and typically depends on history. Endoscopic visualization of a longitudinal scaphoid defect in the anterolateral wall of the cartilaginous lumen can also be helpful in diagnosis (113,131). This defect may also be seen on CT and is believed to be the source of tubal incompetency in symptomatic patients. A variety of medical treatment options have been proposed, including weight gain, discontinuation of decongestants and steroid nasal sprays, mucous thickening agents, and nasal estrogen drops. Surgical interventions include myringotomy and tube insertion, endoscopic peritubal augmentation of ET valve, and surgical closure of the ET lumen (113).

Other Nonvascular Etiologies

Osseous dystrophies of the temporal bone can cause pulsatile tinnitus. Otosclerosis is an osseous dysplasia of the inner ear that leads to stapedial fixation with resulting conductive hearing loss. Cochlear otosclerosis can result in SNHL. The etiology of pulsatile tinnitus resulting from otosclerosis is unknown, but is likely related to inflammation and/or increased osseous vascularization as abnormal foci of vascular Haversian bone replace the normal endochondral layer of the otic capsule (132). Both pulsatile and nonpulsatile tinnitus may be one of the many manifestations of Paget disease of the temporal bone. Pulsatile tinnitus resulting from Paget disease is thought to arise from abnormal bony metabolism and prevalence of intraosseous arteriovenous shunts (61,133).

Abnormalities of the middle ear and tympanic membrane can be found in patients with pulsatile tinnitus, and successful management of these underlying conditions can resolve tinnitus in these patients. Serous otitis media can frequently cause pulsatile tinnitus, due to amplification of cardiac sounds by the occlusion effect induced by fluid within the middle ear space. Similarly, chronic otitis media can yield pulsatile tinnitus. Other anomalies of the middle ear, such as tympanic membrane perforation and ossicular chain abnormalities may be associated with patient complaints of pulsatile tinnitus. The clicking sounds that sometimes accompany temporomandibular joint dysfunction may also lead to rhythmic auditory precepts that can be interpreted as pulsatile tinnitus (4).

Finally, pulsatile tinnitus may be a rare manifestation of intracranial pathology, such as intraventricular cavernous hemangiomas and cerebellopontine angle pathology (including vestibular schwannomas and meningiomas) (5).

HIGHLIGHTS

- Complaints of tinnitus should be divided into subjective versus objective and nonpulsatile versus pulsatile categories to facilitate diagnosis and management.
- All patients with tinnitus should have a complete audiogram as part of their evaluation. Imaging and other studies may be indicated based on findings on history and physical examination.
- Nonpulsatile tinnitus can result from a variety of causes, including SNHL, CHL, ingestion of stimulants, head trauma, and psychiatric disease. When possible, treatment of the underlying cause can alleviate tinnitus.
- When etiology-specific management of nonpulsatile tinnitus fails or is not possible, nonspecific management of tinnitus should be attempted.
- Pulsatile tinnitus can be generated by a variety of arterial and venous causes, vascular tumors, fluid within the middle ear, otosclerosis, and tumors of the IAC. In up to one-third of these cases, no etiologic agent will be identified.
- Treatment of the underlying cause of pulsatile tinnitus, when possible, can resolve this complaint.

Aging and the Auditory and Vestibular System

162

Joe Walter Kutz Jr. *Brandon Isaacson* *Peter S. Roland*

The geriatric population is the fastest growing segment of the population of all industrialized nations, including the United States. As life expectancy increases and health care costs rise, the medical profession will be challenged to provide cost-effective quality care. A recent report by the Institute of Medicine (IOM) predicted the percentage of Americans older than 65 will increase by 20% and double in number from 35 million to 71 million by the year 2030 (1). Since age-related hearing loss is the fourth most common reason patients over 65 years old seek medical care and vestibular dysfunction is common in the older population, there is going to be a substantial increase in the number of outpatient visits for otologic conditions. A recent study by Lin and Bhattacharyya (2) predicted a 30% increase in annual visits to otolaryngologists for otologic diagnoses by 2020. Understanding and treating disorders of the aging auditory and vestibular systems will be more essential than ever for the otolaryngologist.

Greater than 40% of patients older than 65 years have a hearing loss that significantly impairs communication and leads to a decrease in quality of life (3). Loss of hearing negatively affects social interaction, leading to progressive isolation and withdrawal. In addition, high-frequency warning sounds such as alarms and signals may not be heard, resulting in potential harm. Although hearing loss in the geriatric population is often due to presbycusis, other causes should be sought.

Dizziness is the most common presenting complaint in patients 75 years or older and typically affects women more than men (4). Balance disturbances contribute to functional decline in the elderly. Postural stability and gait involves the complex integration of the visual, proprioceptive, somatosensory, and vestibular signals. Pathology in any of these systems can cause dizziness and, more importantly, increase the incidence of falls. It is estimated that approximately 40% of older adults living in the community have at least one fall per year. In a study by the Centers for Disease Control (CDC), 62% of injuries presenting to the emergency department in patients older than 65 years were a direct result of a fall (5). A hip fracture is a common serious injury resulting from a fall and often leads to serious long-term consequences. Only 50% of elderly patients can return home or return to normal activity after a hip fracture (6,7).

The differential diagnosis for dizziness is extensive, sometimes making the evaluation laborious and difficult. However, 90% of the causes of dizziness can be placed in one of seven categories (Table 162.1). One recent study evaluating the cause of dizziness in 677 elderly patients identified benign paroxysmal positional vertigo (BPPV) in 42%, idiopathic vestibulopathy in 20%, migraine-associated dizziness in 13%, Meniere disease in 12%, and an acute vestibular attack in 6%, and 7% contributed to other causes (8).

AGE-RELATED CHANGES IN THE AUDITORY SYSTEM

Auditory Dysfunction

All of the usual cases of hearing loss can affect the elderly (Table 162.2). These disorders are addressed elsewhere in this textbook. With the exception of conductive loss associated with aging as described by Schuknecht, conductive hearing loss in the elderly population has the same differential diagnosis as in younger individuals.

Anatomic changes that affect hearing and balance occur because of physiologic aging. One such example involves the production of cerumen. Cerumen consists of desquamated epithelium mixed with the sebum produced from sebaceous glands and the watery secretions of modified apocrine sweat glands. Modified apocrine sweat glands atrophy with age. Without the watery component, cerumen becomes drier, harder, and less likely to be moved out the external auditory canal (EAC) by the canal's normal transport and cleansing mechanism. The tragi hairs found in adult males become coarser, larger, and more prominent with age. Their

TABLE 162.1 ETIOLOGY OF DIZZINESS

Peripheral vestibular disorders
Cardiovascular disorders
Multisensory dizziness

Neurologic disorders
Psychiatric disease
Hyperventilation syndrome

presence can prevent the natural dislodgement of cerumen from the EAC, contributing to the increased incidence of cerumen impaction in the elderly male.

Presbycusis

The auditory system's durability is determined by genetic resistance and the cumulative imposed physical stress. Genetically mediated hearing loss can be difficult to distinguish from presbycusis. The ability to differentiate hearing loss caused by defective genetic material is increasing

TABLE 162.2 CAUSES OF BILATERALLY SYMMETRIC SENSORINEURAL HEARING LOSS[a]

Ménière disease	Episodic attacks of fluctuant SNHL, vertigo, tinnitus, aural fullness or pressure; bilateral in 20%–30% of cases	History of typical attacks with symptom-free intervals; hearing loss involves low tones initially and later all frequencies, rule out neurosyphilis	Medical Diuretics and low-salt diet Surgical Decompression or shunt of endolymphatic sac; section of vestibular nerve. Penicillin and oral steroids
Luetic hearing loss (late-acquired syphilis)	Often bilateral SNHL with no characteristic audiometric pattern; speech discrimination score often worse than would be predicted on basis of pure-tone thresholds; often associated with vestibular symptoms; may mimic Ménière disease	Positive FTA-ABS test, with or without clinical history of syphilis	
Paget disease	Slowly progressive SNHL and CHL; SNHL worse in high frequencies; maximum CHL of 20–30 dB at 500 Hz	Skeletal deformities of skull and long bones of extremities, elevated serum alkaline phosphatase and urinary hydroxyproline	Calcitonin
Hypothyroidism	Slowly progressive SNHL affecting all frequencies daily	Usual clinical stigmata of hypothyroidism; decreased serum T_4	Desiccated thyroid or Synthroid mixture of T_4 and T_3
Ototoxic drugs	Hearing loss with or without vestibular dysfunction following treatment with known ototoxic drug	History	None
Hereditary progressive SNHL	Progressive SNHL beginning at earlier age than expected for presbycusis; possible positive family history	Family history	None
Noise-induced hearing loss	History of prolonged exposure to loud continuous noise or brief exposure to loud impulse noise	History; characteristic audiogram with maximum hearing loss at 4,000 Hz; may not be distinguishable from presbycusis	None; use of ear protectors may prevent further loss from noise exposure
Head trauma	Severe head injury often resulting in loss of consciousness and bilateral temporal bone fractures	History	None
Cochlear otosclerosis and far-advanced clinical otosclerosis	Far-advanced clinical otosclerosis (stapedial fixation) and cochlear otosclerosis; SNHL may appear on audiogram as severe to profound SNHL; patient will have good speech modulation (unlike in profound SNHL) and will be wearing or will have worn a bone conduction hearing aid; possibly a family history of otosclerosis	History is suggestive but surgical exploration of stapes footplate is diagnostic and therapeutic; poststapedectomy patient may be able to wear ear-level hearing aid with good results	Stapedectomy, sodium fluoride

[a]The hearing loss from any of these diseases may be improved with hearing aids unless it is of such a degree that hearing aids will be inadequate or unsatisfactory. Individuals with bilateral profound SNHL may be candidates for cochlear implant and should be evaluated by an otologist to determine their suitability for such a device.
SNHL, sensorineural hearing loss; FTA-ABS test, fluorescent treponemal antibody test, CHL, conductive hearing loss; Hz, hertz (cycles per second); dB, decibel (arbitrary unit of sound intensity).

TABLE 162.3 FACTORS CONTRIBUTING TO AGE-RELATED HEARING LOSS

Microvascular disease resulting in diminished profusion and hypoxia of labyrinthine hair cells and neurons
Effects of diet; in animals, free radical formation increases hearing loss
Noise exposure
Drug effects
Cigarette smoking

TABLE 162.4 CLINICAL MANIFESTATIONS OF PATHOLOGIC CHANGES WITHIN THE COCHLEA

Cochlear hair cell loss progresses the high-frequency hearing loss with speech discrimination preserved in the initial phases.
Neuronal loss: a nonprecipitous, generalized loss of pure-tone thresholds with speech discrimination impaired out of proportion to the threshold shift.
Atrophy of the stria: flat hearing loss with good preservation of speech discrimination.
Mechanical (cochlear conductive): gradually sloping high frequency hearing loss with speech discrimination impaired proportionate to the pure tone threshold shift.

as the types and tests of chromosomal abnormalities are identified. In any given individual, though, it is difficult to determine what component of the hearing loss is due to inherent genetic determination and what component is a consequence of stresses imposed, such as acoustic trauma, viral infections, otologic disease, vascular diseases, and ototoxic medications. Multiple variables have been evaluated that contribute to hearing loss associated with aging (Table 162.3).

A well-documented phenomenon in elderly subjects is the disproportionate deterioration of speech discrimination for any given pure-tone threshold shift (Fig. 162.1). Tests of central auditory processing include time-compressed speech (word rate per min) and overlapping or interruption of words. These tests suggest that older patients have poorer speech discrimination than younger patients because of changes in central auditory processing. Decreased cell counts in the temporal lobes, increased time required for information processing, and possibly increased transmission time in the central auditory pathways have all been identified as potential factors in central auditory processing disorders in the elderly (9). Elderly patients demonstrate mildly prolonged latencies and reduced wave I amplitudes on the auditory brainstem response (ABR) (10,11).

Schuknecht identified four categories of presbycusis based on clinical and histopathologic changes within the cochlea (Table 162.4):

1. Sensory: epithelial atrophy with loss of sensory cells and the supporting cells of the organ of Corti. Progressive hair cell reduction begins at about age 40. A precipitous decline in pure tone thresholds is seen in the high frequencies.
2. Neural: a reduction in the number of functioning cochlear neurons. Of the 35,500 cochlea neurons at birth, Schuknecht has estimated that 2,100 neurons are lost each decade. When reduction has reached 50% or more of the normal neuronal population, hearing loss develops. This spiral ganglion cell loss also results in a progressive decline in speech discrimination.
3. Strial: atrophy of the stria vascularis. A loss of 30% or more of strial tissue can result in hearing loss characterized by flat hearing loss with relative preservation of speech discrimination.
4. Conductive: alterations of the basilar membrane produce stiffening. The precise nature of these changes is partially hypothesized on the basis of conductive loss that remains otherwise unexplained.

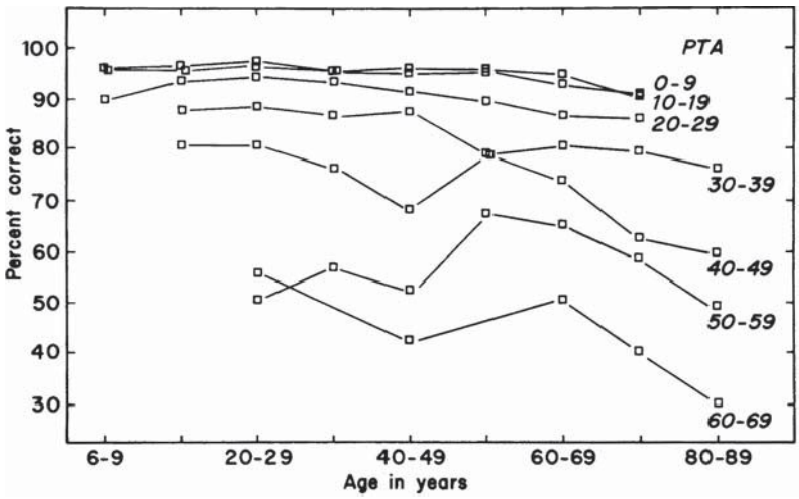

Figure 162.1 Average speech discrimination score as a function of age with the average pure-tone threshold held constant. PTA, pure-tone average. From Jerger J. Audiological findings in aging. *Adv Otorhinolaryngol* 1973;20:115–124.

Although this classification is interesting, each of the four changes may be found to various degrees in any one individual subject; consequently, the audiograms of elderly individuals rarely conform to these classic patterns.

Auditory Rehabilitation

Increased awareness of the prevalence of presbycusis is important, as those with hearing loss tend to be more socially withdrawn and isolated. Patients tend to become frustrated, as do those trying to communicate with them. The main treatment for presbycusis is amplification. Cochlear implantation is an option for some, depending on the severity of the hearing loss. Assistive listening devices (such as FM systems, speaker phones, etc.) are also beneficial. Patient should be instructed to increase the signal-to-noise ratio of their surroundings by reducing the ambient background noise in a room and having someone look directly at them.

The effective use of hearing instruments and cochlear implants is made more complicated in the elderly by commonly associated deficits. Unfortunately, only about 30% of patients who can benefit from hearing aids actually have used them. Decreased vision, cosmetic concerns (feeling "old"), manual dexterity loss, and reduced mobility can make physically removing and adjusting these devices difficult. The financial costs and willingness to wear the devices are additional deterrents for successful amplification. Cognitive deterioration and memory loss can seriously affect an individual's ability to extract maximum benefit from hearing aids or a cochlear implant. Technological advances include total or semi-implantable hearing aids, which may avoid some of the previously mentioned problems experienced with traditional amplification. Refer to Chapter 164 "Hearing aids and assistive listening devices" for a more thorough review of this topic.

AGE-RELATED CHANGES IN THE VESTIBULAR SYSTEMS

Age-related anatomic and physiologic changes to the vestibular system have been described. Age-related degeneration of neural elements in Scarpa ganglia and the vestibular end organs have been demonstrated (12,13). Degenerative changes of the otoconia and reduction in hair cells in the semicircular canals (cristae ampullares) and otolithic organs (saccule and utricle) become more marked with increasing age (14,15). This results in changes in vestibular evoked myogenic potential (VEMP) in older patients characterized by a variable and decreased VEMP amplitude (16–18). Studies evaluating the age-related changes in caloric testing and sinusoidal harmonic acceleration testing are conflicting (19–21).

The key to the evaluation of any patient with dizziness is a detailed description in the patient's own words of the sensation experienced. The subjective character of the dizziness can be classified into four broad categories (Table 162.5):

1. Vertigo (illusion of motion)
2. Presyncope (lightheadedness)
3. Disequilibrium
4. Nonspecific (often psychological disorders)

The time course of the patient's symptoms can provide additional important clues that narrow the differential diagnosis. At the simplest level, one can distinguish between episodic or continuous symptoms. It is helpful to elicit the temporal component of individual attacks as well as the entire course of the disorder:

1. Less than 1 minute: episodes of acute, rotational vertigo lasting less than 1 minute are most commonly associated with disorders of the peripheral vestibular system, such as BPPV.

TABLE 162.5 TYPES OF DIZZINESS

Category	Sensation	Diagnosis
Vertigo	Illusion of motion, either linear or rotating (patient or environment)	Vestibular disturbance attributable to peripheral (BPPV, labyrinthitis) or central (brainstem, cerebellar disease) Cardiovascular disease
Presyncope	Impending faint	Diffuse cerebral ischemia attributable to vasovagal response, cardiac disease, or metabolic disorders
Dysequilibrium	Impaired balance and gaze	Impaired motor control due to neuromuscular disease, severe bilateral vestibular disease, stroke, multisensory deficits, or medications
Nonspecific	Light-headedness, "confusion," "wooziness," "fuzzy-headedness"	Often psychological disorders (anxiety, depression, panic), hyperventilation

2. Less than 1 hour: Vertigo lasting a few minutes to an hour or two can be secondary to Ménière disease, transient cerebral hypoperfusion, migraine headaches, or phobic/anxiety disorders.
3. Several hours to 24 hours: This type of dizziness also suggests migraine headaches or Ménière disease. Viral or vascular labyrinthitis usually presents with acute rotational vertigo of several days duration, with gradual improvement.
4. Greater than 24 hours: Migraine-associated dizziness, vestibular neuritis, chronic subjective dizziness, or other central or metabolic causes.

HISTORY AND PHYSICAL EXAMINATION

Before making a diagnosis in an elderly patient, the otologist needs to perform a thorough history and physical examination. Presbyastasis and presbycusis are diagnoses of exclusion; other pathologies must be ruled out. Associated otologic symptoms discussed with the patient include hearing loss, tinnitus, aural fullness, otorrhea, and otalgia. Patients also need to be asked about a history of significant noise exposure/trauma (e.g., loud music, gunfire, etc.), prior otologic/head and neck surgery, and a family history of hearing loss. Because of the high incidence of systemic illnesses in the elderly population, a detailed past medical and surgical history is obtained; one should inquire about the presence of neurologic or ophthalmologic diseases, which can create symptoms of dizziness. A detailed inquiry should be obtained about systemic disorders that potentially interfere with cerebral blood supply that may produce vertigo due to either focal brainstem involvement or diffuse cerebral ischemia. Cardiac abnormalities (e.g., arrhythmia, valvular regurgitation/stenosis) can cause presyncopal episodes. Systemic illnesses such as diabetes mellitus, hypothyroidism, human immunodeficiency virus infection, and sexually transmitted diseases can also result in vestibular symptoms and should be queried. The patient should be counseled to follow-up with their primary care physician for the above conditions and to meet CDC guidelines for screening tests and immunizations. Patients who present with complaints of dizziness should be asked about a prior history of falls and if they are experiencing problems with driving.

A thorough history of prescription, nonprescription, and alternative medications is assessed. A social history is critical and should include an assessment of alcohol, caffeine, salt, tobacco, and illicit drug use. Cardiovascular drugs such as diuretics, beta-blockers, and vasodilators may produce presyncope and orthostatic symptomatology. Ototoxic drugs (e.g., aminoglycosides such as gentamicin) typically cause disequilibrium and oscillopsia. Alcohol can cause postural hypotension resulting in presyncope. Psychiatric medications, muscle relaxants, and anticonvulsants also have been associated with disequilibrium (Table 162.6). Polypharmacy is a significant issue in the elderly and may be a potential cause of vestibular symptoms.

A complete neurologic examination including a peripheral vestibular assessment should be performed in patients presenting with dizziness. Refer to Chapter 165 "Clinical evaluation of the patient with vertigo" for more thorough review. Otomicroscopic exam is done to rule out middle ear disease, cholesteatoma, or temporal bone tumors. A head and neck exam is done to rule out a concomitant otolaryngologic abnormality. A directed systemic (cardiovascular) examination may also be performed. Dix-Hallpike testing with Frenzel lenses should be performed. Drachman (22) advocates the use of the Dizziness Simulation Battery in the office evaluation of dizziness (Table 162.7). The patient is asked to identify which of eight different maneuvers most closely reproduces a patient's dizziness. This test battery includes an assessment of hyperventilation, orthostatic hypotension, peripheral vestibulopathy, carotid sinus simulation, and multisensory disorders. Carotid sinus stimulation should be avoided in the clinical setting due of the risk of syncope and cardiac arrhythmias. The elderly patient with complaints of vertigo may suffer from any of the disorders found in younger individuals (e.g., BPPV, acute labyrinthitis, and Ménière disease) but more often typically has a multifactorial aspect to his or her symptoms.

TABLE 162.6 MEDICATIONS THAT CAN PRODUCE OR EXACERBATE BALANCE DISTURBANCE

Drug Class	Type of Dizziness	Mechanism
Alcohol	Unsteady gaze, positional vertigo	Cerebellar and vestibular dysfunction
Sedatives, anxiolytics	Nonspecific lightheadedness	CNS depression
Antihypertensives	Presyncope	Orthostatic hypotension
Antiepileptics	Dysequilibrium	Cerebellar dysfunction
Aminoglycosides	Dysequilibrium, oscillopsia	Labyrinthine hair cell damage

TABLE 162.7 DIZZINESS SIMULATION BATTERY

Cardiovascular
- Orthostatic blood pressure testing
- Potentiated Valsalva maneuver (produces presyncope)
- Carotid sinus stimulation

Vestibular
- Dix-Hallpike maneuver (only produces vertigo in patients with positioning vertigo)
- Barany rotation (stimulates horizontal semicircular canals, producing vertigo in anyone who retains some vestibular function)

Multisensory
- Walk and turn
- Seated head turn

Psychiatric
- Hyperventilation (30 s)

CONDITIONS CAUSING VESTIBULAR DYSFUNCTION IN THE ELDERLY

BPPV is the most common cause of dizziness among elderly and has been reported to be the cause for vertigo in up to 39.1% of patients over 70 years old (23). A cross-sectional study found a 9% incidence of unrecognized BPPV in an elderly population (24). As in younger patients, the posterior semicircular canal is most commonly affected, although any canal can be involved. The presence of BPPV in the elderly is significant since these patients have a 78% prevalence of suffering a fall (24).

The reason for an increased incidence of BPPV in the elderly population is multifactorial. It has been demonstrated the mass and number of otoconia declines with age with the saccule affected more severely than the utricle (25). In addition, decline in calcium metabolism manifested by osteopenia and osteoporosis may have resulted in a loss of otoconia volume in the elderly (26,27). Finally, decreased vascular supply to the otolith organs is more common in the elderly population and may be associated with vertebrobasilar insufficiency or migraine headaches (28–30).

Cerebrovascular insufficiency caused by ischemia of the labyrinth or central vestibular nuclei may result in episodes of acute vertigo associated with focal neurologic deficits such as dysphagia, hemiparesis, dysarthria, headache, or blurred vision. The diagnosis is clinically based and includes the presence of focal neurologic deficits. It can arise as a consequence of reduced flow caused by arteriosclerotic disease in the vertebrobasilar system, or it can arise as a consequence of compression of the vertebral arteries from cervical osteoarthritis.

A brainstem stroke may present as paroxysmal vertigo with unremitting nausea and vomiting, but a brief neurologic examination typically will uncover other neurologic deficits. Even so, patients are occasionally released from the emergency department with an inaccurate diagnosis because the patient may only be aware of the fact that even small, brief head movements precipitate overwhelming vertigo, nausea, and vomiting. Patients may be unaware of the other neurologic deficits produced by the infarct. Fortunately cerebrovascular disease is an uncommon cause of isolated dizziness with a recent study showing an incidence of less than 1 in 500 patients having a major cerebrovascular event within a month after being discharged from the emergency department when presenting with a chief complaint of dizziness (31).

Orthostatic hypotension occurs only when the patient assumes the standing position from the supine or sitting positions. By strict criteria, orthostatic hypotension requires a 20-mm Hg decrease in systolic pressure and a10-mm Hg reduction in diastolic pressure 3 minutes after standing. The sensitivity and specificity of this test has been debated. Many patients have subjective disequilibrium, vertigo, and presyncope without ever meeting the strict definitional criteria. A cardiologist may perform tilt-table testing if the diagnosis is still suspected. Postural hypotension arises from pooling of blood in the lower extremities because of decreased tone. The chronic use of antihypertensive agents, prolonged bed rest, and autonomic dysfunction can all produce orthostatic hypotension. Vasovagal attacks (fainting) may be induced when strong emotions activate the brainstem medullary vasodepressor centers. Vagal hyperactivity causes a decreased cardiac output, leading to a decrease in cerebral blood flow. Decreased cardiac output because of arrhythmia, congestive heart failure, myocardial infarction, and valvular disease (such as aortic stenosis) may lead to the presyncopal type of lightheadedness.

Bilateral symmetric vestibular loss results in persistent unsteadiness. This type of imbalance is typically worse in the dark, when visual cues are not available to help compensate for the loss. Bilateral vestibulopathy can arise from ototoxic drug exposure but also occurs as an idiopathic degenerative disorder. Proprioceptive and somatosensory loss can produce disequilibrium that is worse in the dark. It is often secondary to peripheral neuropathy (common in patients with diabetes mellitus or renal failure).

Osteoarthritis of the cervical spine may cause disequilibrium due to spinal stenosis with spinal cord compression. Such patients often demonstrate bowel and bladder dysfunction. Degenerative disease of the cervical spine may also produce a sense of disequilibrium and imbalance because of altered proprioceptive feedback from muscle stretch receptors and position sense receptors in the muscle and joints of the cervical spine.

Lesions of the frontal lobes or basal ganglia cause disequilibrium often associated with weakness, rigidity, or tremor. Cerebellar lesions cause severe disequilibrium with or without visual cues and are often associated with visible nystagmus, a wide-based gait, and truncal ataxia.

Parkinson disease, common among the elderly, produces characteristic postural and motor abnormalities resulting in a festinating gait. These patients usually stand in a posture of flexion with the thoracic spine bent forward and the head bent down. With forward locomotion the patient takes short, shuffling steps that become successfully more rapid, and the patient may fall without assistance. This disturbance of posture and motor control often results in disequilibrium. The postural instability typically does not respond to levodopa.

Multisensory impairments are due to impaired physiologic function in several systems simultaneously and are more common in the elderly than in the young. Modest disturbances in each of these systems may synergize to produce postural instability and disequilibrium out of proportion to the individual deficits. Subjects with multisensory impairments typically present with a sense of disequilibrium during standing or walking. Multidisciplinary care involving the geriatric specialist, cardiologist, neurologist, vestibular physical therapist, and ophthalmologist may be warranted.

Hyperventilation is often a consequence of anxiety or phobic disorders. Diffuse cerebral ischemia results from constriction of the cerebral vasculature caused by decreased carbon dioxide in the blood. Anxiety and panic disorders, adjustment reactions, and depressive disorders are the most common diagnoses. Such patients often describe a chronic feeling of "wooziness." Two mechanisms have been proposed by Sloane: (a) Patients with underlying primary psychological disorders may be more susceptible to impairment by diseases affecting neurosensory systems, and (b) dizziness symptoms themselves impair function and may cause secondary psychological problems. Management consists of treating the appropriate underlying disorder when present.

DIAGNOSTIC EVALUATION

In straightforward cases (e.g., posterior canal BPPV), the diagnosis is easily determined by a careful and detailed history and physical examination. An audiogram is a relatively inexpensive but useful screening tool. In patients with vague symptoms, complicating histories, and significant comorbidities, a vestibular evaluation is recommended. This may include electronystagmography or videonystagmography, rotary chair testing, ABR, electrocochleography, VEMPs, and computerized dynamic platform posturography. Refer to Chapter 144 "Balance function tests" for a more thorough discussion of the evaluation of dizziness. Radiologic studies (CT and/or MRI scans) may be ordered as deemed necessary, especially with asymmetric otologic complaints.

MANAGEMENT

A sensation of imbalance and a fear of falling lead to a greater level of inactivity and social isolation, worsening the quality of life in a group of people who may have already lost spouses, friends, and other social support systems because of their age. When possible, treatment is directed at the underlying cause of the dizziness, as described under those conditions. Sometimes, however, the only available option is nonspecific therapy directed at symptom control. In general, medical therapy for patients with an acute loss of vestibular function is aimed at controlling the acute vestibular and autonomic symptoms. Five main classes of drugs are used: antihistamines (e.g., meclizine), phenothiazines (e.g., promethazine), anticholinergics (e.g., scopolamine), 5HT3 antagonists (e.g., ondansetron), and benzodiazepines (e.g., diazepam). All drugs should be administered sparingly and for short durations (1 to 2 weeks) because they can cause a reduction in central nervous system (CNS) compensation. Meclizine is typically administered in doses of 12.5 to 25 mg orally three times per day as needed for acute, peripheral vertigo of long duration. Benzodiazepines (usually diazepam at 2.5 to 7.5 mg daily in divided doses) suppress vestibular output of the vestibular nuclei.

Benzodiazepines are the most effective vestibular suppressants. 5HT3 antagonists may be helpful if nausea and/or vomiting are prominent symptoms. However, there is no evidence of 5HT3 receptors within the vestibular system. Phenothiazines can be administered rectally if nausea and/or vomiting does not allow oral intake of medications. All medication should be used cautiously in the elderly, to avoid CNS side effects. Many of these classes of drugs share a similar side effect profile. Antihistamines, phenothiazines, and anticholinergics all share the propensity to produce sedation, dysphoria, and disorientation. If combination therapy is used, care is taken to avoid synergy of side effects. Many geriatric patients are already taking drugs with anticholinergic or sedative side effects. The interaction of vestibular suppressants with these medications is carefully considered.

Vestibular rehabilitation has been an effective therapy for more than 50 years (32–34). In addition, it can be used in conjunction with other types of physical therapy and exercise. Many of the problems associated with aging may be due primarily to inactivity. It is thought that some of the aging process itself can be slowed by exercising and physical activity. Vestibular rehabilitation involves specific habituation exercises designed to enhance the normal adaptive mechanisms in the CNS. The benefits of vestibular rehabilitation are not affected by a patient's age (35). The goal of vestibular rehabilitation is fall prevention. One in three elderly individuals living in the community fall each year. Hospital or nursing home patients fall twice as often as those who are not in these settings. Vestibular symptoms precede falls in more than 50% of these patients. Program strategies vary depending on the patient's primary problem, but they are aimed at stabilizing gaze and posture, improving CNS adaptation, conditioning, and providing emotional and psychological support. The principal components of effective vestibular rehabilitation include gaze

stabilization, balance retraining, and desensitization. Each aspect is addressed separately using different exercises.

Gaze stabilization exercises promote vestibular adaptation through exercises that stimulate the vestibuloocular reflex. Balance retraining starts with activities that progressively decrease the patient's base of support and progress to gaze exercises performed on varied surfaces (e.g., stairs, foam, balance beams). The balance system is challenged by having patients attempt to walk through crowded hallways. Strengthening exercises are prescribed to improve muscle strength and flexibility. Given the buoyancy of water, swimming pool exercises provide a safe environment in which the elderly can exercise. Repetitive head and arm movements designed to promote vertigo and unsteadiness in a safe and predictable environment enhance the CNS adaptive mechanisms. These exercises are repeated until they are well tolerated or are not providing additional meaningful improvement. Over a 6- to 8-week course, the number of repetitions is slowly increased. Vestibular rehabilitation is administered by a physical therapist with special expertise in treating vestibular disorders in the elderly. These rehabilitation strategies are effective in positional vertigo and to compensate for sudden loss of vestibular function (after recovery from an acute attack and after vegetative symptoms have disappeared). These exercises also provide improved function and mobility in patients with multisensory deficits.

ABLATIVE THERAPY

Patients who continue to suffer from incapacitating, lifestyle-limiting dizziness despite maximum medical therapy may be candidates for chemical (gentamicin) or surgical ablative therapy, such as labyrinthectomy or vestibular nerve section. Ablative therapy has very limited utility and benefit in patients without Meniere disease. Recovery from unilateral loss of vestibular function is felt to be slower and less complete in the geriatric population and postprocedure rehabilitation is recommended to optimize recovery.

SUMMARY

More than 12.5 million people over the age of 65 in the United States are thought to be significantly affected by dizziness or balance disturbances. Dizziness is the most common presenting complaint in patients over 75 years of age. The majority of the geriatric population with dizziness has multifactorial causes. It is important that one be familiar with the differential diagnosis, evaluation, and potentially multidisciplinary management of these disorders. It is inappropriate to attribute symptoms such as dizziness to the aging process alone; a complete evaluation must be performed. The otologist should be prepared to make referrals to a neurologist, audiologist, cardiologist, ophthalmologist, or psychiatrist and work in conjunction with the primary care physician to provide a full evaluation and comprehensive care.

HIGHLIGHTS

- Aging produces changes in the auditory and vestibular system that result in loss of function.
- Alterations in the physiology of the EAC lead to a dramatically increased incidence of cerumen impaction in the elderly.
- Presbycusis is multifactorial.
- Presbycusis is a diagnosis of exclusion; other causes should be sought.
- Elderly subjects with presbycusis may have degradation of speech discrimination out of proportion to pure-tone loss.
- Amplification and cochlear implantation can significantly improve the quality of life for elderly patients.
- BPPV is the most common cause of vertigo in the elderly population.
- Dizziness is the most common presenting complaint in patients over 75 years of age.
- A specific cause of dizziness and vertigo can be found in 85% of elderly patients.
- The differential diagnosis of balance disturbance in the elderly can often be rapidly narrowed by determining if they describe symptoms of true vertigo, presyncope, chronic disequilibrium, or of nonspecific complaints.

163 Cochlear Implants and Other Implantable Auditory Prostheses

Oliver F. Adunka *Craig A. Buchman*

Over the past few decades, cochlear implants and other active auditory prosthetic devices have helped revolutionize the fields of otolaryngology, audiology, and other hearing-related specialties. Generally, these prosthetic devices can be thought of as either *hair cell stimulators* when the native auditory system is driven by way of amplification of the acoustic signal or *neural stimulators* when electrical currents are applied directly to or in close proximity to the auditory neural tissues. These devices should be distinguished from prostheses that are passive conductors of acoustic energy such as ossicular reconstruction and stapes prostheses. Hair cell stimulation devices are, by design, for patients with sufficient hair cell populations and thus residual hearing. By contrast, neural stimulators are for patients with hair cell populations that are insufficient for acoustic stimulation but neural populations that are preserved. Clearly, areas of overlapping indication exist for these devices. Moreover, these concepts are beginning to be combined to achieve even greater performance for individual patients.

Hair cell stimulators activate the auditory system by increasing the transfer of acoustic energy to the inner ear through hearing aids, active middle ear implants (MEIs), and osseointegrated auditory implants. Acoustic amplification can be delivered to the tympanic membrane in the external auditory canal by conventional hearing aids. By contrast, active MEIs are placed on the ossicular chain or windows of the inner ear to deliver acoustic energy to the functional hair cells, thus bypassing the external auditory canal and tympanic membrane. Osseointegrated implants are placed distant from the otic capsule and conducting ear structures and stimulate the inner ear through osteoconductive forces delivered by setting the skull bone in motion.

Auditory neural stimulators include cochlear implants, auditory brainstem and midbrain implants. Cochlear implants are for patients with preserved auditory nerve populations and are usually placed longitudinally within the cochlear lumen, in close proximity to the distal nerve fibers. These devices rely heavily on the tonotopic arrangement of the neural fibers within the cochlea for discrete frequency-specific (i.e., place) stimulation. The auditory brainstem implant (ABI) can be used for patients in whom the auditory nerve is absent or unavailable for stimulation. This device's electrodes are applied either on the surface of or within the cochlear nucleus of the brainstem at the foramen of Luschka at the pontomedullary junction. Finally, the midbrain implant, which remains investigational, would possibly be indicated for individuals in whom the cochlear nucleus is not available for stimulation because of pathologic or surgical insults. In all three instances, speech processors are used to convert environmental acoustic signals into electrical stimulation strategies that might be appropriate for the neural tissues in question.

Clearly, cochlear implants are the most successful prosthetic solution to replace the function of a sensory organ and have helped (re)habilitate many thousands of patients with hearing loss. The success of this intervention is derived mostly from a sustained research and development effort for more than 40 years, the lack of other effective treatments for patients with severe to profound hearing loss, and the presence of a viable cochlear nerve in nearly all patients. Through auditory electrical stimulation, these devices have allowed patients with congenital and acquired deafness to obtain sound awareness and enhanced speech understanding in both quiet and noise, thereby drastically improving educational and employment opportunities, social integration, and overall quality of life. This chapter provides a detailed overview of cochlear implants and other auditory prosthetics that are currently being used in patients today.

COCHLEAR IMPLANTS

Overview

The modern cochlear implant is a device designed to convert environmental sound into electrical impulses that are delivered along a multiple electrode array situated in close proximity to the cochlear (auditory) nerve. Since the distal cochlear nerve fibers are arranged along the tonotopic, longitudinal axis of the cochlea lumen, application of discrete electrical stimulation at progressively deeper stations results in variably lower, psychophysical frequency percepts. As this paradigm does not necessarily rely upon hair cell transduction mechanisms, it is ideal for patients with significant hair cell loss. Since most patients with sensorineural hearing loss maintain some degree of functional auditory nerve fibers, these devices are particularly well adapted for most etiologies of hearing loss. Given the need for surgery and the effectiveness of hearing aids for lesser degrees of hearing impairment, the cochlear implant has been reserved for patients with significant degrees of hearing loss that are not easily rehabilitated with conventional amplification.

Outcomes for cochlear implantation can be defined in terms of sound awareness, enhancement of lipreading, improvements in speech perception, quality of life, and cost-effectiveness. Broader outcomes for adults include improvements in socialization, employment opportunities, income, and overall health and well-being (1–4). For children, extended outcomes include speech and oral language production, educational setting and achievement, the need for specialized services, and safety (5–7). Recently, expanding indications for implantation and combining the electrical stimulation of a cochlear implant with native acoustic stimulation are broadening the application of this technology.

Historical Aspects

The first electrical stimulation of the inner ear probably was performed by Count Alessandro Volta at the end of the 18th century when he placed two metal rods in his ears and connected them to the terminal of 30 or 40 electrolytic cells (~50 V). He reported the sensation of "une secousse dans la tete" or a blow on the head followed by a sound like "the boiling of a viscid liquid" (8). Djourno and Eyries are credited with the first intralabyrinthine implantation of an electrical stimulating prosthesis. This was placed through a labyrinthine fistula in a patient with chronic otitis media and cholesteatoma in Paris in 1957. Djourno was a French neurophysiologist and Eyries an established otologist. Upon stimulation, the patient described high-frequency sounds that resembled the "roulette wheel of a casino" and "crickets." Their patient was able to discern the words "pap," "mamm," and "allo" (9–11).

In 1957, a patient in Los Angeles, CA, brought William House, MD, a news article detailing the apparent success of Djourno and Eyries. By 1960 and 1961, House with his colleagues Doyle and Doyle experimented with electrical stimulation of the inner ear. House performed promontory and vestibule stimulation of patients undergoing stapedectomy surgery (12). Using a square-wave generator, he noted that patients could detect auditory percepts from electrically delivered currents better in the perilymph of the vestibule than on the promontory. Direct stimulation of the perilymph did not cause dizziness or facial stimulation above 30 Hz. In the 1960s and 1970s, numerous other groups were exploring the field of electrical stimulation of the inner ear, primarily for the purpose of hearing. Teams including F. Blair Simmons and Robert White (Stanford University); Donald Eddington (University of Utah); Robin Michelson, Michael Merzinich, and Robert Schindler (University of California at San Francisco); and Claude-Henri Chouard (France) and Graeme Clark (University of Melbourne) were most active. In contrast with House, these efforts were mostly directed at developing a multichannel electrode CI (13–18).

Blair Simmons, MD, with the assistance of Epley at Stanford (1964) implanted six electrodes in the modiolus portion of the eighth nerve near the basal cochlear fibers under local anesthesia (19). Electrical stimulation resulted in some auditory percepts. Following these initial experiments, House and Doyle implanted two adult patients with single gold electrodes for short-term stimulation of hearing. One additional patient received a 5-electrode device. All three of these devices were later removed because of compatibility issues (12). Specifically, the wires were tracked through the skin and resulted in local wound infection and irritation.

At the University of Paris as well as the Universities of Utah and California at San Francisco (UCSF), percutaneous connectors attached to intracochlear electrode arrays allowed for stimulation to be carried in a variety of ways ultimately allowing for great advances in the development of signal processing strategies (14,15,17). Ultimately, however, similar to the experiences of House and Simmons, these devices required removal because of local infection. Importantly, it was clear that the percutaneous connection was unsustainable and that an alternative method for energy and data transfer was needed.

House later teamed with engineer Jack Urban to produce the first wearable, "take home" cochlear implant, implanted in Chuck Graser in 1972 (12,20). This was possible because of the use of newer, biocompatible materials developed in the pacemaker industry. His initial device was a five-wire electrode grounded through the footplate of the stapes. He was ultimately fitted with a speech processor/stimulator that had a single electrode that delivered a 16-KHz sinusoid carrier wave. While this implant as well as the one used by Michelson (21) at UCSF failed to produce open-set speech perception, these devices proved that simple transcutaneous, inductive coupling was possible and that a percutaneous connection was not needed (21).

Dobelle et al. (22) later proposed a single radiofrequency (RF) link for both data and power transfer. In 1974, the University of Melbourne produced an electromagnetic dual link for data and power transfer that was highly efficient. This method allowed for transcutaneous, efficient transfer of power and data and is currently used in the Food and Drug Administration (FDA)-approved systems that are clinically available today in the United States (US) (23).

Creating a hermetically sealed device was a major challenge for early investigators. Graeme Clark and colleagues in Melbourne (1974) melted glass on to wires that exited a Kovar steel container that housed the circuitry (24). This was unsuccessful as fluid leakage persisted. In the pacemaker industry, epoxy resin was also unsuccessful. K. Kratochivil at Telectronics, a pacemaker company in Australia, discovered that when a blend of ceramics was sintered, it would bond to both wires and the metallic container to produce an impermeable seal. For Cochlear Corp in Australia, this technology when used in combination with a titanium package for strength produced the hermetically sealed device that is in use today. However, this construct required moving the data transmission antenna to a remote site, creating an elongated device with a susceptible antenna connection (24). After implanting their initial multichannel prototype device in 1978, great strides were made in the 1980s demonstrating the superiority of these place-coding devices over the single-channel implants of House (25–29). From this time forward, place coding using multiple electrodes situated longitudinally along the course of scala tympani to stimulate the tonotopic organization of the cochlear nerve became the preferred approach (30–32).

From Clark's work arose Cochlear Corp, the largest manufacturer of cochlear implants in the world today. In 1984, the Australian multichannel cochlear implant was introduced into the market and approved for adult usage by the FDA. In 1990, the criterion was extended to children older than 2 years of age. Over the next decade, the FDA-approved minimum criterion for age of implantation in children was lowered to 12 months.

With the help of Ingeborg and Erwin Hochmair in Vienna, Austria, Kurt Burian implanted a multichannel device in 1977. From this effort grew the company MED-EL corporation. In California, the work at UCSF by Michelson, Merzinich, and Schindler progressed to form Advanced Bionics Corporation (Sylmar, California, USA), the only US-based cochlear implant manufacturer. For both Advanced Bionics and MED-EL Corporations, a ceramic housing was chosen so the antenna and electronics were included in the same package. Unfortunately, ceramic was more brittle and susceptible to cracks in response to external trauma. The welding of ceramic to the metal header also created a relative weak point for the hermetic seal. Over time, the ceramic construct of these devices has given way to the silastic–titanium devices that are in use today by all three implant manufacturers producing FDA-approved CIs in the US.

Over the last 30 years, electrode and speech processor developments have produced more effective stimulation strategies associated with successively higher performance levels. Further miniaturization of components has resulted in small, behind-the-ear speech processors and very thin, atraumatic electrodes that preserve intracochlear structures.

In the early 2000s, bilateral cochlear implantation as well as implantation with preservation of significant acoustic residual hearing has broadened the indications for these devices. Moreover, combining acoustic stimulation with that of the electrical signal provided by the cochlear implant has begun to produce results for patients that had previously not been considered possible (33–36). Today, sound localization, hearing in noise, and even music appreciation are becoming possible.

In 2005, a totally implantable cochlear implant was developed in Sydney and implanted in Melbourne, Australia, as a part of a research project conducted by Cochlear Ltd and the University of Melbourne (37). This was the first cochlear implant system capable of functioning for sustained periods with no external components. Because this device used a subcutaneous microphone, significant attenuation of the signal and interference with bodily noise limited wide-scale application. Nonetheless, the stage has now been set for a fully implantable cochlear implant. With further advances, it seems probable that one day, normal hearing might be restored through combinations of technology without the need for visible external hardware.

In the 1960s and 1970s, considerable opposition arose within the scientific community regarding the possibility of speech understanding by patients with cochlear implants. Specifically, "auditory physiologists and histopathologists dismissed these investigations as misguided attempts by surgeons—who know little about auditory neuroscience to stimulate nerves that were already dead" (26). Moreover, the deaf community identified cochlear implants as an unacceptable intervention that "didn't work" and ultimately threatened a child's right to be deaf—a cultural right (38). Over time, combining considerable improvements in technology, indications, and results with the fact that most deaf children are born to two hearing parents who want their child to communicate in an auditory–oral way has made this opposition to cochlear implants lessen. Today, cochlear implants are widely regarded as an accepted and efficacious choice for patients who are deaf or significantly hearing-impaired.

Principles of Electric Stimulation of the Auditory System

The current cochlear implant design consists of an external device (microphone, speech processor, headpiece) and an internal, implanted device (receiver–stimulator, multichannel electrode array) that communicates across intact skin by way of RF. The internal and external device

antennas are aligned for transmission by integrated magnets. The microphone detects sound and transmits the information to a signal processor. The processor includes a series of filter banks that use fast-Fourier transforms to partition the acoustic signal into the respective frequency bands and decodes the information into an electrical signal. The signal is processed according to a predefined strategy, amplified, and compressed to match the narrow, electric dynamic range of the ear and sent through the intact skin to the implanted receiver–stimulator. The electrode array that is inserted within the cochlear lumen is hardwired to the receiver–stimulator package. The longitudinal arrangement of the cochlea along a frequency spectrum (basal→apical corresponds to high pitch→low pitch regions) allows for frequency-to-place mapping. Inside the cochlea, electric impulses at the electrodes stimulate neural elements, bypassing the nonfunctioning hair cells. Thus, high-frequency information is converted to frequency pulses that are delivered to basal electrodes, while progressively lower-frequency information is relayed to more apical locations. Today, combinations of temporal and place coding account for most of the stimulation strategies in use. Temporal coding is only beginning to be implemented in newer Hilbert transformation paradigms.

Coding Strategies

The earliest speech-coding strategy used by the House-3M single-channel device employed amplitude modulation of a 16-kHz sinusoid by the bandpass-filtered audio input signal. The incoming signal needed to be compressed to cope with the limited dynamic range for electrical stimulation of the auditory nerve. Even though most of the original temporospectral information of the analog signal was preserved, the signal transfer to the auditory nerve was limited by the maximal firing frequency of the nerve in response to the electrical stimulation at a single site within the cochlea. High synchronization of nerve fibers and the neural refractory period only allowed for frequency transmission up to 1 kHz via pure temporal coding. For higher frequencies, the spectral information could not be sufficiently transferred. While these single-channel devices provided sound awareness and enhancement of lipreading, open-set speech perception was rarely achieved, thus paving the way for the frequency-place coding that is used in all of the multichannel devices on the market today (39).

The earliest multichannel place-coding devices used bandpass filters to separate frequency bands and compression to reduce the needed acoustic dynamic range in to the electrical stimulation range of the cochlear nerve (~20 dB). However, these devices remained limited by current spread and channel interaction, thereby limiting spectral resolution. Poor spectral resolution probably contributed to significant spectral mismatch between the frequency allocation to a given electrode and the perceptual consequences of stimulation. Attempts to improve this spectral mismatch have included moving the site of electrode activation closer to the neural elements by creating modiolar conforming arrays, intraneural electrodes, light stimulation, or neurotrophic factors (40–42). Another approach has been to use multiple electrode activation at differing times (i.e., temporal coding) to avoid channel interactions, thereby improving stimulation specificity.

Today all of the modern strategies use some variation of pulsatile (on–off), interleaved stimulation of the multiple electrodes within the array in an effort to achieve specific stimulation while avoiding channel interaction, thereby improving frequency selectivity. That is, spatially separate electrodes are activated at different times to account for neural refractory times, current spread, and electrical field interaction. These strategies are commercially known as continuous interleaved sampling (CIS), advanced combination encoder (ACE), Spectral Peak (SPeak), and HiResolution (HiRes) and are individually employed by all three cochlear implant manufacturers, in their products. The primary differences among them are rate of stimulation, number of channels, the relation between the number of filters and the number of electrodes activated, as well as the details of how each channel's envelope is extracted and how much of the acoustic signals temporal information is preserved. SPeak and ACE attempt to emphasize spectral peaks in the signal by selecting a subset of filter outputs with higher energy levels. HiRes augments the envelope with temporal information by allowing higher-frequency components through the envelope detector. Although some patients can clearly perform better with one strategy than another, average speech scores across populations of patients do not clearly demonstrate superiority of a particular strategy (43).

Pathologic Basis for Success

Cochlear implantation usually results in a loss of residual acoustic hearing, presumably from intracochlear trauma induced through cochleostomy or electrode insertion, disruption of the endocochlear potential, or delayed reaction to the foreign body. A variety of evidence has demonstrated traumatic disruption of the cochlear endosteum, spiral ligament, stria vascularis, basilar membrane, osseous spiral lamina, and even modiolar fractures (44–49). Trauma and bone dust may also induce further changes in the inner ear including fibrosis and osteoneogenesis. Such intracochlear changes can potentially increase impedance values and stimulation requirements and alter psychophysical percepts. These changes might also reduce future abilities to reimplant the cochlea or the patients to consider other biologic therapies (50–55). A variety of investigations support the site of stimulation to be the spiral ganglion cell body. Moreover, most evidence demonstrates little correlation between spiral ganglion cell number and speech perception abilities using a cochlear implant. Most recently, new tissue formation in the cochlea has been associated with the degree of neurosensory element loss. These findings suggest

that atraumatic electrodes and surgical approaches and techniques should continue to be sought in the future (48).

Current Device Technology

Currently, there are three major companies that produce cochlear implants in the US. The devices from each implant manufacturer and some of the various differences among them are outline in the Table 163.1. Comparative data between the various devices are sparse or completely lacking making efficacy claims regarding technological superiority theoretical. As these comparative data are lacking, patients are left to choose technology based on factors other than performance including reliability, aesthetics, operational characteristics, surgeon and center preference, and word-of-mouth communication amongst users.

Patient Selection

Absolute contraindications to cochlear implantation include those patients without either a cochlea (Michel aplasia) or a cochlear nerve. Relative contraindication might include those patients with active middle ear disease, severe anesthetic risk, and too much residual hearing or those who are unwilling to tolerate the surgical risks.

There are clearly patients who may require adjustment of expectations through more detailed counseling prior to considering surgery as their prognosis for attaining high-level open-set speech perception might be more limited. Patients at risk for lower level performance might include those with either anatomic disorders that can adversely affect the electrode-neural interface or central nervous system problems that result in impaired auditory processing or cognitive impairment. Examples of the former category include (a) *cochlear disorders* such as extensive cochlear obstruction from previous meningitis, otosclerosis, or severe inner ear malformation and (b) *cochlear nerve disorders* such as cochlear nerve deficiency (CND) or tumor of the 8th cranial nerve (i.e., vestibular schwannoma). *Central nervous system disorders* that might adversely affect normal brain function and thus performance with the implant could include previous stroke, degenerative diseases such as multiple sclerosis, dementia, tumors, or infections. With these caveats in mind, it is critical to recognize that setting appropriate expectations for potentially lower levels of performance are *not contraindications* to surgery. Rather, restoration of audition through cochlear implantation can result in dramatic improvements in quality of life and daily function for these individuals but should be undertaken following appropriate counseling of expectations. In certain instances, assessment of psychological factors can be useful to better understand a patient's condition prior to considering implantation.

In the US, at least three different bodies have separate guidelines for establishing what constitutes candidacy criteria for cochlear implantation in adults and children. These include the US FDA who recognizes the results of appropriate safety and efficacy clinical trials carried out by the device manufacturers to achieve specific labeling for their product(s), insurance companies, and the Centers for Medicare and Medicaid Services. In general, adults (≥18 years) are required to have a moderate-to-profound hearing loss without medical contraindications and the desire to be a part of the hearing world. The results for aided speech perception testing vary by manufacturer and payer and are listed in Table 163.2. Prelingual children can be as young as 12 months of age, gain limited benefit from amplification, while being enrolled in an early intervention program. Older children with some degree of speech perception should also have specific speech perception testing results that are obtained while wearing appropriate amplification (Table 163.3). It is clear that candidacy criteria continue to evolve as technology improves and new

medical discoveries uncover broadened indications. The reader should always seek up-to-date, detailed information on a case-by-case basis prior to considering candidacy.

For young children, it remains critically important to recognize the importance of early intervention in the form of appropriately fit amplification and/or cochlear implantation in the development of speech perception, speech production, and spoken language (5). While these studies clearly document the fact that earlier is better, this must be balanced against the reality that cochlear implants, in their current format, usually result in a total loss or substantial decrement in native acoustic hearing abilities in the operated ear. While electrophysiologic methods are sufficient for estimating the degree of residual hearing for the purposes of fitting amplification, there remain some patients who have no responses on auditory brainstem response (ABR) and auditory steady state response testing who can gain enough benefit from amplification for the purposes of speech and language development (56,57). With this in mind, it remains important to defer cochlear implantation until the age where developmentally appropriate behavioral audiometric results are valid (usually 7 to 9 months of age for visual reinforcement audiometry). One clear indication for very early implantation might include a history of meningitis with ongoing ossification. Irrespective of the type of intervention, early diagnostic and therapeutic auditory-based speech therapy is critical in assessing progress in spoken language development. This single factor remains of paramount importance in deciding whether to proceed with implantation in the very young, hearing-impaired child.

Temporal Bone Imaging in Cochlear Implantation

Diagnostic imaging of the temporal bone and brain is critical in patients considering cochlear implantation to (a) identify the etiology of hearing loss, (b) define surgical anatomy and the potential for complications or sequelae from surgery, and (c) identify factors that negatively impact upon prognosis for performance using the device. Even in the setting of a normal history and physical examination, it is not unusual for routine preoperative temporal bone imaging to identify conditions such as developmental labyrinthine anomalies, CND, otosclerosis, and inflammation, fibrosis, and ossification of the inner ear.

Imaging protocols for both high-resolution magnetic resonance imaging (MRI) or computed tomography (CT) of the temporal bones and brain have been described previously (58–62). From an imaging perspective, developmental labyrinthine anomalies are well-defined using either MRI or CT. However, MRI is superior to CT for identifying CND in the setting of a normal dimension internal auditory canal, inner ear luminal obstruction when ossification is lacking (i.e., fibrosis), and central nervous system disorders such as vestibular schwannoma, demyelinating disease, and stroke. Conversely, CT is better for determining

TABLE 163.3 DEVICE LABELING BASED ON SPEECH PERCEPTION TEST RESULTS IN CHILDREN

the degree of labyrinthine obstruction that is due to ossification (i.e., calcified), cochlear nerve aperture patency in the setting of a small internal auditory canal, and facial nerve location within the temporal bone (58,59,61–63). Thus, we prefer MRI to CT for patients with an uncomplicated history as this modality can identify a patent cochlea and normal cochlear nerve while avoiding radiation exposure. CT is used selectively when cochlear obstruction is present, the internal auditory canal is small, the semicircular canals are absent resulting in facial nerve anomaly, and when temporal bone pathology is present. MRI is avoided in patients with pacemakers or severe claustrophobia.

Labyrinthine anomalies have been described in detail previously (64,65). In these cases, cochlear structure can be normal, absent (Michel malformation), cystic, incompletely partitioned (IP), or hypoplastic. Semicircular canals can be either aplastic or dysplastic. The vestibular aqueduct or endolymphatic duct and sac can be enlarged (EVA) in isolation or in association with cochlear IP. This group is referred to as the *IP-EVA spectrum*. If all cochlear partitioning is absent but there remains differentiation in to cochlear and vestibular labyrinthine compartments, this is termed as cystic cochleovestibular malformation (CCVA). Common cavity (CC) is defined as no internal differentiation of the labyrinth into either a vestibular or cochlear compartment. Examples are shown in Figure 163.1.

CND refers to a small or absent auditory nerve on high-resolution imaging and has been identified among patients with normal inner ear morphology as well as those with inner ear malformations, narrow internal auditory canals, and/or electrophysiologic characteristics of auditory neuropathy spectrum disorder (ANSD) (60,66–68). Figure 163.2 shows examples of CND in the setting of a normal and small internal auditory canal.

Cochlear obstruction can occur following previous cochlear inflammation in the setting of meningitis and

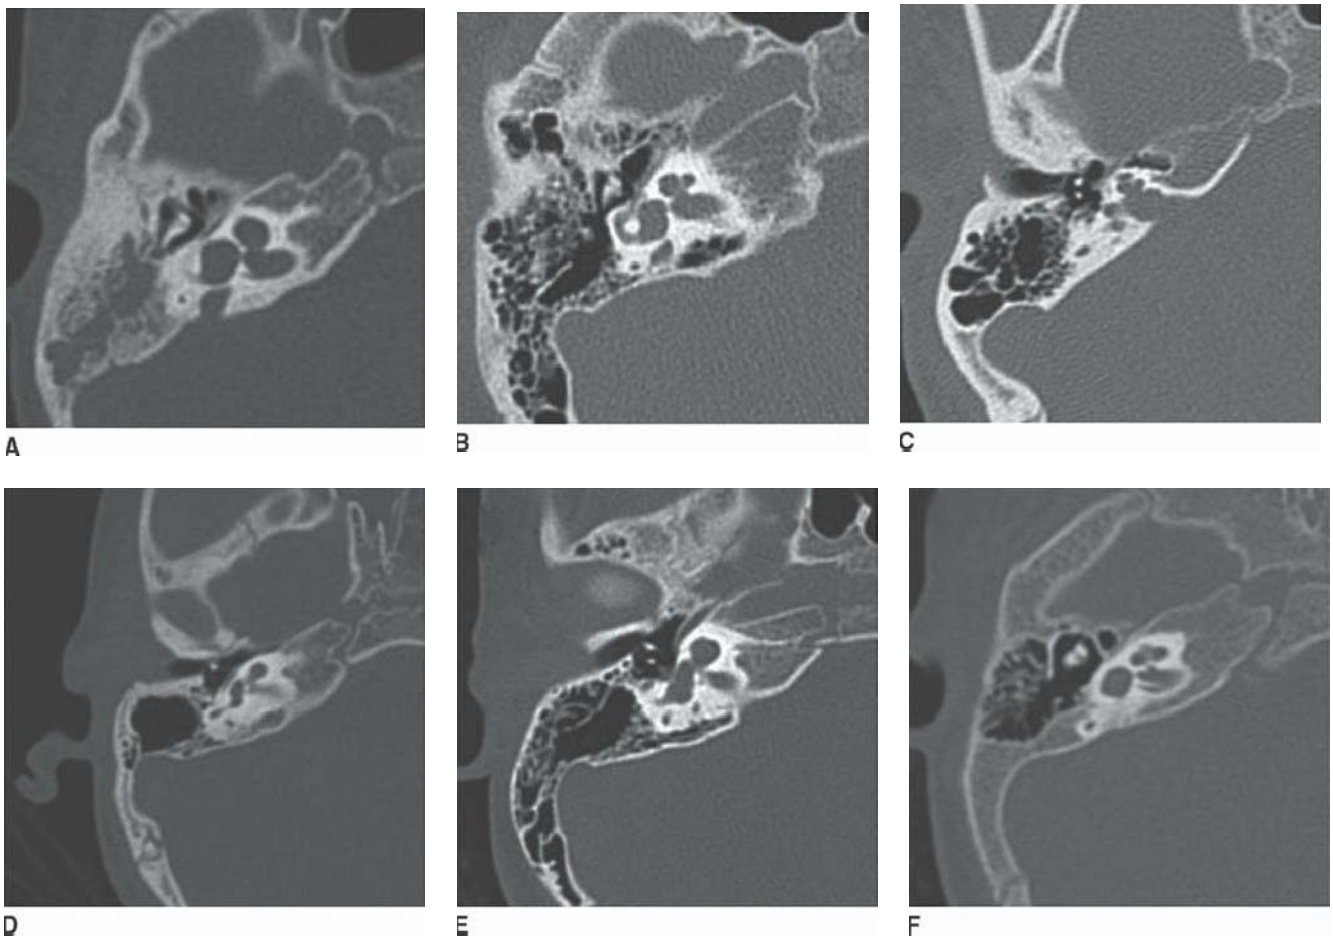

Figure 163.1 Axial CT images demonstrating various inner ear anomalies, including incomplete partition **(A–C)**, cochlear hypoplasia **(D–F)**, and cochleovestibular malformations **(G,H)**. In incomplete partition, there are normal cochlear external dimensions, but decreased or absent partitioning. Type I **(A)** has absent internal divisions; type II **(B)** has apical fusion with a present interscalar septum (called Mondini type when the vestibular aqueduct is enlarged); type III **(C)** is X-linked stapes deafness type. Hypoplastic cochleas have smaller external dimensions: Type I **(D)** is bud-like hypoplasia; type II **(E)** is cystic hypoplasia; type III **(F)** is a cochlea with less than two turns. If all cochlear partitioning is absent but there is differentiation into cochlear and vestibular compartments, the malformation is termed a CCVA *(Conitnued)*

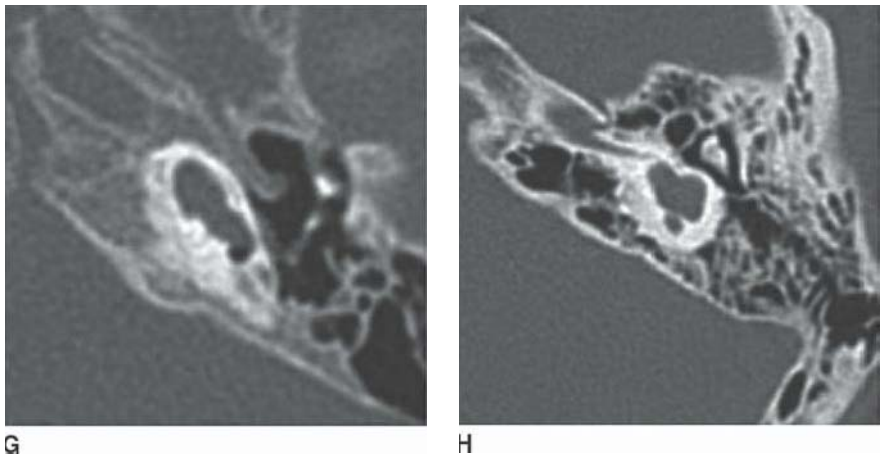

Figure 163.1 (*Continued*) **(G)**. If there is no internal differentiation of the labyrinth into vestibular and cochlear compartments, the malformation is called a CC **(H)**.

immune-mediated inner ear diseases such as Cogan syndrome or following severe cases of otitis media. Secondary ossification within the fibrotic inner ear lumen can subsequently result in solid obstruction. In such cases, neural viability can be suspect. Examples of cochlear inflammation, obstruction, and ossification are seen on both MRI and CT (Fig. 163.3).

Surgery for Cochlear Implantation

Setup

Cochlear implant surgery is performed under general anesthesia and typically takes between 1and 2 hours to complete. Patients with significant medical comorbidity should have a prior anesthetic risk assessment. Before surgery, a clear middle ear space should be confirmed through otoscopy, tympanometry, and/or temporal bone imaging to insure that the device will not be exposed to bacterial pathogens that can create future infectious complications. Facial nerve monitoring is routine for all surgeries. Perioperative antibiotics are given 30 minutes before skin incision. A first-generation cephalosporin is sufficient as ear pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa* should be unusual in routine cases. In instances in which common middle ear

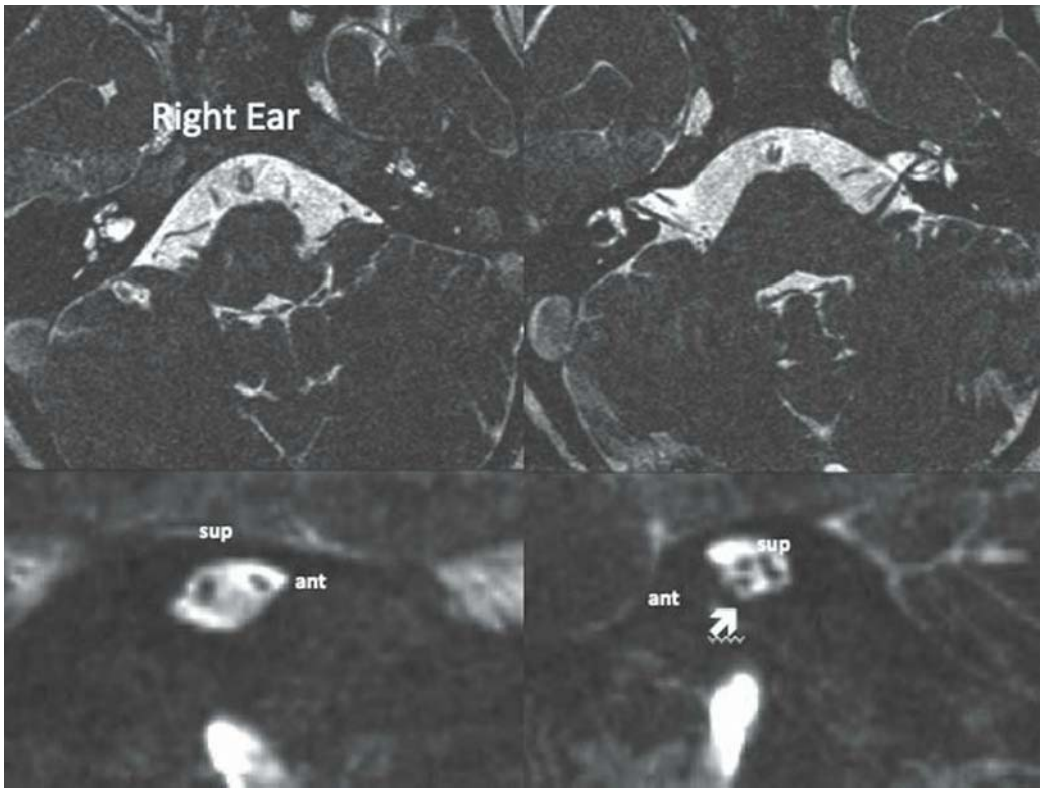

Figure 163.2 CND. High-resolution volumetric T2-weighted MRI demonstrates an absent cochlear division of cranial nerve VIII in the right ear on both the axial images and the oblique sagittal reconstructions oriented perpendicular to the internal auditory canal. The *arrow* indicates the normal contralateral cochlear nerve.

pathogens might be present, broader-spectrum coverage should be considered.

Preparation

The patient is situated in a supine position with the head turned to expose the postauricular region. Shaving of hair is mostly unnecessary. Prior to skin incision, local anesthetic with vasoconstrictor is infiltrated in the postauricular region. The skin incision is planned to achieve successful placement of the receiver–stimulator in a position that is remote from the pinna and mastoid (Fig. 163.4). Locating the receiver–stimulator too close to the pinna can result in unwanted interaction between the magnetic headpiece and the speech processor. Moreover, placement too close to the mastoid can be problematic if skin retraction in to the mastoid results in unwanted device exposure. The use of manufacturer-specific device templates prior to the incision can help locate the proper position. Focal injection of methylene blue through the skin and on to the bone allows for identification of the bony position for the internal device after skin elevation. Locating the device relative to the mastoid cavity following bony exposure can be ineffective since mastoid size varies considerably among individual of all ages. The final position of the receiver–stimulator usually is significantly superior and posterior to the pinna. The long axis of the device creates roughly a 45-degree incline from the horizontal through the zygomatic arch.

Receiver–Stimulator Placement and Fixation

Following a skin incision, a subperiosteal pocket is created in the proposed region for the internal receiver–stimulator that is bounded inferiorly by the lambdoid suture and is

Figure 163.4 Typical skin incision used for cochlear implantation. A similar incision is used for active MEIs. Larger incisions have been used in the past but are currently not used anymore.

strictly sized for the device being implanted (69). A bony depression can be created according to the device templates and the device fixed to bone by any one of a variety of methods (70). For adults, nearly all techniques are sufficient, while for children, simple suturing of the periosteum provides rigid fixation to bone and avoids intra- or transcortical drill holes or screws that might put the underlying dura or venous sinuses at risk (71).

Approach

A standard mastoidectomy is performed. The facial recess is opened maximally using the horizontal semicircular canal, fossa incudis, chorda tympani, and facial nerve as landmarks. The facial nerve usually can be visualized through the bone without exposing it. The round window niche overhang is initially identified as a bony, rounded ridge located inferior to the oval window niche and anterior–inferior to the stapedius tendon. The niche is always located posterior to Jacobson nerve on the cochlear promontory and 1 to 2 mm inferior to the oval window. It is very important to recognize that limited opening of the facial recess can result in an inferior view towards the hypotympanum with a resulting look at the air cell system rather than the promontory and round window region. With adequate opening, the round window niche overhang is removed to expose the round window membrane, the primary landmark to scala tympani.

Cochleostomy

When describing the surgical technique for cochleostomy creation, one should keep the basic objectives in mind: open scala tympani (and not scala vestibuli), minimize collateral trauma to physiologically relevant intracochlear structures, and provide a relatively straight insertion trajectory along the longitudinal axis of the basal turn in an effort to allow for buckle-free electrode insertion. Currently, a variety of differing cochleostomy techniques exist that can be adapted to the clinical situation depending on the following: the electrode array to be used, the cochlear morphology, and the desire for hearing preservation (72).

An adaptive cochleostomy approach is used whereby electrode arrays that are long, rigid, and inserted with a stylet or rigid insertion tool are placed through a separate cochleostomy (Fig. 163.5). Such a cochleostomy is always round window related and might actually communicate with the round window membrane if higher insertion forces are not anticipated. For very long electrode arrays that are designed for complete cochlear coverage, a cochleostomy that has circumferential bony walls or a round window membrane insertion is acceptable. In these cases, cochlear length rather than cochleostomy location probably determines whether insertion resistance will be encountered. For cases in which a shorter array is to be used in a hearing-preservation capacity, openings that include the round window membrane are the rule (Fig. 163.5). The details of cochleostomy choice and creation are covered in Basura et al. (72).

Electrode Insertion

A smooth, resistance-free insertion of the proposed electrode array in to patent scala tympani is the goal of most implantations. A variety of tools exist for the various devices that are available. The reader is referred to the individual surgical manuals for details regarding usage of the various devices. In general, a standard jeweler's forceps are an excellent tool for most array insertions.

Telemetry and Imaging

Following device placement and wound closure, device interrogation is carried out using the manufacturer's software. All devices have telemetry programs that allow for measurement of electrode impedances and electrically evoked compound action potentials. Impedance measures are useful for identifying open circuits. If a substantial number of circuits are found to be open, replacement of the device should be considered to insure that an adequate number of electrodes are available for stimulation. While electrically evoked compound action potential testing is probably not useful in routine adult cases in which cochlear nerve populations are not in question (73), this technique might provide useful information in cases of possible neural compromise such as ANSD, inner ear malformations, or CND. In such cases, the result of these measures has been shown to correlate with future performance on open-set speech perception measures (67,74). Moreover, threshold determination for electrically evoked compound action potentials might identify a useful stimulation starting point for very young children.

Special Surgical Considerations

Inner Ear Malformations

Congenital inner ear malformations are common (10% to 20%) among children undergoing cochlear implantation (75). Labyrinthine anomalies have the potential to adversely affect the electrode-neural interface, reduce electrode array insertion depths, predispose to cerebrospinal fluid gusher through the cochleostomy, and be associated with facial nerve anomalies that can create access problems for scala tympani. The variety of inner ear malformations, as identified on temporal bone imaging, have been detailed above and are demonstrated in Figure 163.1 (63,65,75).

A transmastoid facial recess approach can be used in most instances of inner ear malformation except when a CC is present. In these cases, a transmastoid labyrinthotomy can be used (Fig. 163.6). Similar to cases without malformations, a round window–related cochleostomy can usually be created. A variety of electrodes are available for these special cases. In general, when a cochlear interscalar septum is lacking, modiolar conforming electrodes should probably be avoided (Fig. 163.1).

Cerebrospinal fluid gushers from the labyrinth are common is children with inner ear malformations, especially those with IP-EVA spectrum findings on imaging.

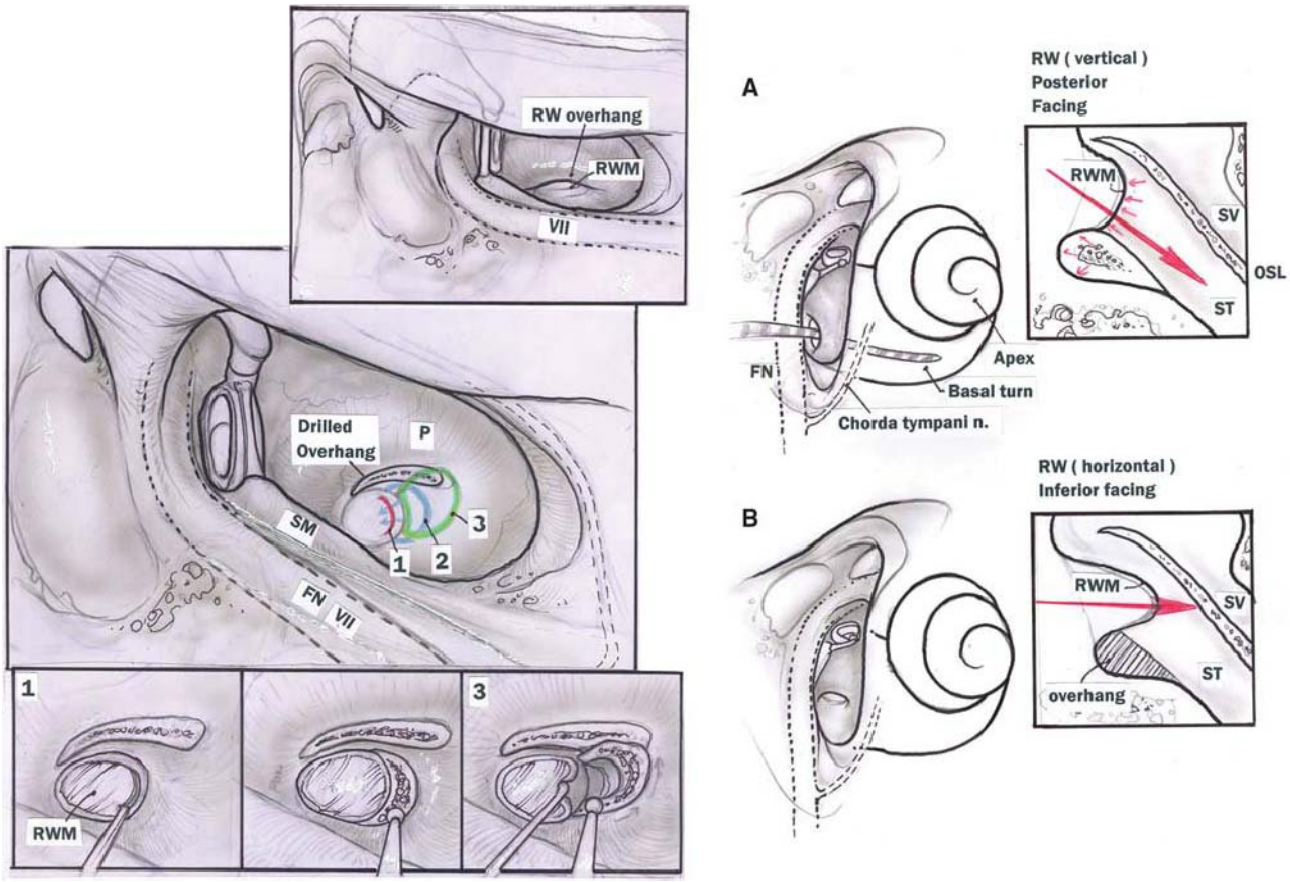

Figure 163.5 **(A)** Illustration demonstrating the position of the round window as seen through a typical facial recess. The bony overhang covering the actual window has to be removed to expose the actual membranous window. Also, the actual window is often covered by fibrous tissue layers making exposure more difficult. The center image shows different cochlear openings. *1*: round window incision. *2*: inferior enlargement of the round window. *3*: separate round window–related cochleostomy. The bottom images demonstrate the respective techniques. **B:** Illustration of typical insertion trajectories through the different round window alignments. Specifically, the round window membrane can assume a more vertical position (*a, top images*). In these cases, the window faces essentially posterior facilitating a direct insertion through the window. In some other temporal bones, the round window assumes a more horizontal position (*b, bottom images*), which generates a very perpendicular view onto the membrane through the facial recess. In these cases, the electrode can take a trajectory heading towards the bony modiolus.

Of interest, the cochlear morphology in most instances does not predict the gusher except when the modiolus is absent (Fig. 163.1). In such instances, creating a larger cochlear opening and tightly packing connective tissue around the electrode array is sufficient. Cerebrospinal fluid diversion is not needed if the leak is controlled intraoperatively. Electrode array insertion should be carried out only to the point of first significant resistance. Imaging that reveals a hypoplastic cochlea should be expected to have limited electrode insertion depths and for these cases, shorter arrays are helpful.

Children with absent semicircular canals or external auditory canal atresia can create significant issues for cochlear access since the facial nerve is often times displaced anteriorly. In these instances, the mastoid antrum can be indistinct, the ossicular chain malformed, the cochlea is usually hypoplastic with possible CND, and the round window niche completely obliterated by the facial nerve. Children with CHARGE association are particularly predisposed to this situation, and special care should be exercised in considering implantation in these children. Figure 163.7 shows an intraoperative picture of such a case.

Inner Ear Obstruction

Cochlear obstruction can occur following inner ear inflammation from meningitis, immune-mediated ear disease, otitis media with labyrinthitis, or trauma. In these cases, the cochlear lumen can be narrowed or obliterated with fibrous tissue or bone. Preoperative imaging with MRI and CT will usually reveal the extent to which such obstruction exists and the approach needed for implantation. In cases of ongoing meningitis, intervention should be considered in the early stages so as to avoid total obstruction and inability to implant the ear(s) in question. Moreover, consideration should also be given to bilateral implantation at the initial surgery.

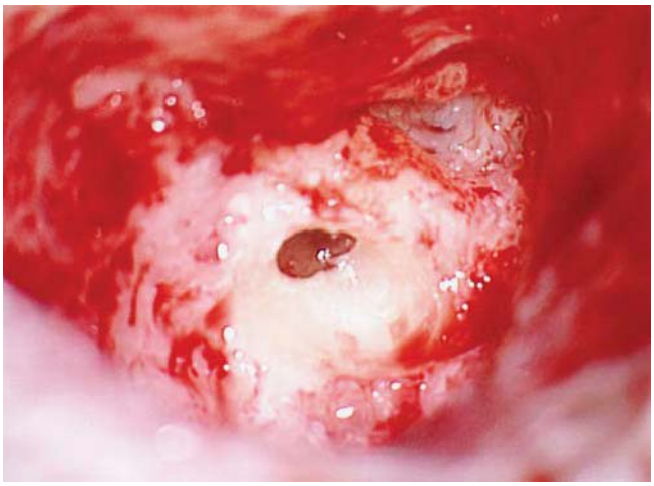

Figure 163.6 Labyrinthotomy approach for cochlear implantation in a case of a CC malformation. The lateral semicircular canal typically used as a surgical landmark cannot be used. Instead this single opening into the cavity should allow the surgeon to curl the electrode inside to generate an optimal electrode–neural interface.

Approach to implantation of the obstructed cochlea should be considered in a stepwise manner. Following routine round window exposure, the membrane often time appears white, indicating underlying pathology. In cases of short segment obstruction resulting from either fibrosis or bone (1 to 3 mm), a typical round window–related cochleostomy can be created by drilling through the short segment of obstruction. Array insertion can usually proceed in a normal fashion. If more than 3 mm of drilling fails to reveal a patent cochlear lumen, a scala vestibuli insertion should be considered by moving superiorly, above, and anterior to the round window region (Fig. 163.8). Usually scala vestibuli insertions can accommodate a complete electrode array. Rarely, severe first turn ossification can make both scala tympani and vestibuli inaccessible at the cochlear base. In such situations, a double array can be used. In this situation, the trough created near the round window can be used for a short array. An apical cochleostomy is also created for an upper, retrograde insertion. This opening is made anterior to the oval window, inferior to the cochleariform process. Great care should be exercised to avoid inadvertent injury to the undersurface of the labyrinthine segment of the facial nerve. Following such insertions, communication with the individual programming the device is critical to insure that proper pitch assignment is made for the retrograde electrodes. Finally, in cases of diffuse obstruction, a circummodiolar drill out is possible (76,77).

Figure 163.7 Surgical view of a left ear with a displaced facial nerve. Specifically, the nerve (*arrow*) runs over the round window niche and the cochleostomy can be seen anterior to the nerve. All semicircular canals are absent in this case.

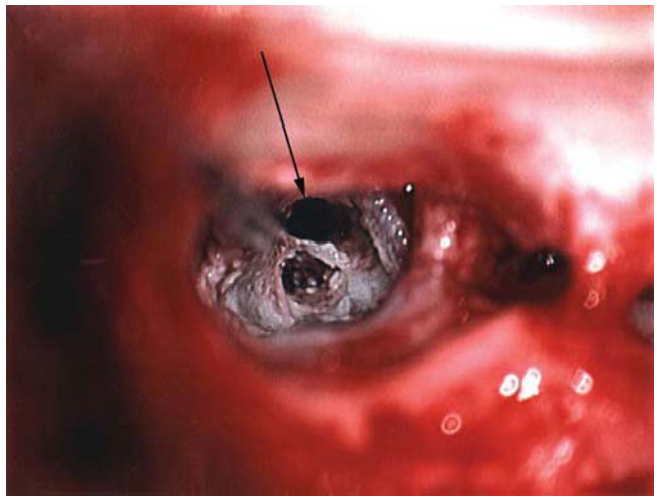

Figure 163.8 Surgical view (left ear) through the facial recess in a case of postmeningitic ossification. A cochleostomy (*arrow*) into the basal turn's scala vestibuli has been furnished superior to the initial attempt into scala tympani, which revealed ossification of the lumen.

Otitis Media

Active otitis media is a contraindication to cochlear implantation in that intracochlear or device exposure to viable bacteria can result in suppurative labyrinthitis with subsequent meningitis and ossification. Moreover, device colonization can result in subsequent wound infection, breakdown, and hardware loss.

In children, consideration of active middle ear disease is common in the winter months. The middle ear space should be assessed prior to skin incision in all cases. In cases of acute otitis media, delayed intervention is justified. If recurrent disease is probable, tympanostomy tube insertion is reasonable with delayed implantation. There are some advocates for subtotal petrousectomy with blind sac closure in the setting of otitis media to avoid future considerations for this problem. There also remains considerable dispute regarding the significance of otitis media with effusion. In cases of serous effusion, the incidence of bacterial colonization is probably very low. Conversely, in cases of mucoid effusion, delayed intervention is prudent.

Cochlear implantation in the setting of chronic suppurative otitis media with or without cholesteatoma remains

a difficult problem. In such cases, active middle ear disease should be cleared or controlled prior to implantation. One option is to consider early blind sac closure with or without obliteration and staged implantation. This avoids the long-term issues of tympanic membrane retraction, granulation, infection, and electrode exposure within a tympanic membrane perforation.

Complications

Fortunately, complications are unusual following cochlear implantation today. Complications might be broadly categorized in to those that are *medical/surgical* in nature and those that are *device-related*. The categories are detailed in Table 163.4. Historically, medical/surgical complications were more common than device-related issues. This was primarily due to the fact that flap/wound complications were common when postauricular wounds were large, devices were rigid, and location of the receiver–stimulator was too close to the mastoid cavity. With surgical advancements, these issues have become decidedly rare. Minimal approaches to skin incisions and proper device location and immobilization have been key in reducing such complications. Careful attention to the surgical details described above can avoid or at least minimize many of the surgical complications outlined.

Common and potentially unavoidable complications include taste disturbance from chorda tympani nerve manipulation or sacrifice (~10%), transient dizziness (~10% of adults and less common in children), and subcutaneous seroma (10%) (78). The vestibular effects of cochlear implantation have long been a concern among otologic surgeons. Fortunately, complete vestibular deafferentation remains uncommon following surgery, especially when cochleostomy location is in scala tympani and attention is paid to electrode insertion vectors and force application (72,79,80). For children, the risk of vestibular loss remains quite small since most pediatric patients have limited, peripheral vestibular function preoperatively. Subcutaneous seroma, while common early after cochlear implant surgery nearly always resolves without the need for any intervention.

Device-related complications include receiver–stimulator hard failures, suspected device malfunction (i.e., soft failures), and open circuits. *Hard failure* refers to a total lack of function of the device despite properly functioning external equipment. Hard failures results from internal, receiver–stimulator problems and require revision surgery to alleviate the issue. Suspected device malfunction or *soft failure* is significantly more difficult to diagnose and refers to the situation where despite the presence of auditory percepts, the patient experiences aversive symptoms such as pain, shocking, atypical tinnitus, or a decrement in function. Following complete exchange of the external equipment and confirmation of electrode location within the cochlear lumen by imaging, an internal device problem is suspected and revision surgery considered if the symptoms are intolerable to the patient. A soft failure is also considered a clinical device failure. Open circuits can occur early or in a delayed fashion following cochlear implant surgery. A value judgment of electrode number and location is needed to insure adequate stimulation is available for performance. The details of revision cochlear implantation and reliability are often times complex. Fortunately, in most instances, revision cochlear implantation results in a functioning device that restores access to sound. In many instances, such surgery also allows for an upgrade in technology. However, it is critically important to realize that revision surgery during the formative years of a child's development can result in a significant setback in speech perception, production, and language thereby delaying educational achievement. Parents of such children should be made aware of these possible delays prior to surgery (81).

Meningitis in Cochlear Implant Recipients

The incidence of meningitis in cochlear implant recipients is greater than that of an age-matched cohort in the general population (82,83). Risk factors in this population include young age, the presence of inner ear malformations, and the use of a two-part electrode system. The risk of meningitis also appears to be higher among individuals with sensorineural hearing loss without a cochlear implant although this risk appears lower than that of implanted

TABLE 163.4 COMPLICATIONS OF COCHLEAR IMPLANTATION

Device-Related	Medical/Surgical
Internal Hard Failure (i.e., dead device)	Flap wound (infection, extrusion)
Internal suspected malfunction (i.e., soft failure)	CSF gusher or leak
Speech processor failure	Dural or vascular injury
Accessories malfunction (cables, headpiece, etc)	Incomplete electrode insertion
Open electrode circuits	Electrode extrusion
	Facial nerve injury

patients (84). It remains difficult to determine whether cochlear implantation *per se* confers an increase risk of meningitis in subjects without the factors cited above.

The most common organism identified in postimplantation meningitis is *S. pneumoniae*. All potential routes of spread (middle ear, inner ear, hematogenous) should be considered in such a patient. Recent animal investigations into the mechanisms of meningitis following cochlear implantation suggest that all three routes are viable sources for such an infection (85). These works also support the need to create a relatively atraumatic cochlear opening, insert the electrode array without trauma to reduce the potential for inner ear to subarachnoid space communication, and form an adequate seal at the cochleostomy with connective tissue to prevent the direct spread of infection along the array. Moreover, experimental results of pneumococcal vaccination in implanted animals support the current recommendation by the FDA and implant manufacturers for early vaccination in all cochlear implant candidates and recipients (86). Early and adequate treatment of otitis media is also important in preventing meningitis in implanted patients.

Clinical Results

Cochlear implantation is an auditory intervention that restores sound awareness for nearly all individuals that receive the device. Depending on a variety of factors and expectations, there remains a wide range of performance outcomes that are achievable through cochlear implantation. These include enhancement of lipreading and improvements in speech perception and music appreciation (87–89). Improved speech perception can result in appropriate development of spoken language and educational achievement for children and improved communication skills for adults (5,6). Many adult patients with cochlear implants can also talk on the telephone using their device (~75%). These outcomes secondarily enhance employments opportunities, socialization, and quality of life (1). Moreover, the cost-effectiveness of this intervention is astounding (1,3).

Outcomes from cochlear implantation depend heavily on the development of appropriate expectations among families and patients. A variety of patient factors, surgical factors, implant center factors, and access to appropriate rehabilitation appear to be drivers in success. Patient factors remain the single most important variable in determining outcomes. Some of the factors that should be considered include age, age of onset of hearing loss (deafness), duration of deafness, medical comorbidities, etiology of deafness, anatomic cochlear and cochlear nerve status, cognitive abilities, behavioral condition, psychological factors, parental desires and involvement, educational setting, and resources among others. Of these factors, the duration and severity of auditory deprivation prior to cochlear implantation remains the single most important. Long-standing auditory deprivation creates a number of biologic changes within the auditory system that are not easily reversed despite restoration of auditory inputs. Timely intervention thus remains paramount for both children with congenital deafness all individuals with deafness onset later in life. For those with less than complete deafness, the degree of residual acoustic hearing also seems important at predicting outcome with a cochlear implant (90). While age at implantation appears to be associated with outcomes, this variable more than likely reflects the duration of auditory deprivation rather than being an independent factor. Thus, implantation among the elderly is not contraindicated. Other patient factors that can adversely affect outcomes include comorbidities such as cerebral palsy, psychomotor retardation, cognitive abilities, motivations, and compliance. Unfortunately, socioeconomic factors also seem to play a role in access and outcomes from this technology (91,92).

A key factor in achieving the best outcomes from cochlear implantation is the ability to create an appropriate electrode-neural interface. Both patient factors and surgical factors can alter this situation. Inner ear malformations, CND, inner ear obstruction and ossification, can reduce neural elements available for stimulation. In such instances, outcomes can be less than similar patients without these factors (67,75,93). Recently, preliminary data suggest that electrode location within the normal structure inner ear can also be important factor in performance (55,94,95). Surgeons should aspire to achieve atraumatic electrode placement in an effort to preserve neural elements and thus improve performance.

ANSD is a clinical syndrome characterized the presence of normal outer hair cell function, as revealed by the presence of otoacoustic emissions and/or cochlear microphonic on electrophysiologic testing, and aberrant or disordered neural conduction in other sites along the auditory pathway. A variety of genetic or acquired conditions can lead to the clinical phenotype. More than 50% of children with ANSD have a history of prematurity (74,96). Over the years, there has been some controversy regarding the effectiveness of hearing aids and to a lesser extent cochlear implants in children with this disorder. Recent work suggests that both hearing aids and cochlear implants can be effective in many of these children (74,97). However, there remains a subset of children with ANSD who are poor performers. These children frequently have other associated neurologic conditions such as progressive blindness, peripheral neuropathy, or evidence of CND on high-resolution imaging (74,75,98).

There are a number of potential advantages and disadvantages to bilateral cochlear implantation in both adults and children (Table 163.5). Bilateral cochlear implantation significantly improves hearing in noise and sound localization abilities in both adults and children. Moreover, bilateral implantation reduces time spent "off the air." These benefits are critical for young children who rely on

TABLE 163.5 ADVANTAGES AND DISADVANTAGES OF BILATERAL COCHLEAR IMPLANTATION

Bilateral Cochlear Implants

Advantages	Disadvantages
Always implant better ear	Two surgeries
Hearing in quiet	One or two anesthesias
Hearing in noise	Loss of acoustic hearing
Never off the air	Bathtub hearing
	CI limited frequency spectrum
	Future therapies
	Vestibular effects
	Double programming
	Economics

incidental hearing for learning. As in unilateral implantation, there also appears to be a critical period for developing binaural skills implying that second ear implantation should be considered early in young deaf patients (99). It remains to be determined whether bilateral implantation is superior to unilateral implantation in patients who can effectively use a contralateral hearing aid (i.e., bimodal hearing). Research is ongoing in this area (100–102).

Finally, cochlear implants are being placed in patients with progressively greater degrees of residual hearing using special electrode arrays and surgical techniques that allow for preservation of residual acoustic hearing. The combination of electric and acoustic stimulation in the same ear (electroacoustic stimulation or hybrid implantation) has been an active area of investigation for nearly the last decade (33,35,103). While the devices needed for this approach remain to be approved by the FDA, preliminary results seem very promising. Significant improvements in hearing are evident both in quiet and in noise when compared to similar cochlear implant recipients that have undergone conventional, non-hearing preserving implantation (104). It seems evident that the future of cochlear implantation will include hearing-preservation surgery for all patients undergoing the procedure. Challenges for this intervention will rely on making implantation with preservation of residual acoustic hearing highly reliable and precise for combining such stimulation. Areas such as automated electrode insertion and intraoperative monitoring of hearing are promising areas of investigation.

Summary

Cochlear implants are a remarkably successful prosthetic intervention for patients with sensorineural hearing loss not sufficiently managed with conventional, high gain amplification. Cochlear implants use multielectrode arrays to restore audition through auditory nerve stimulation within the tonotopic confines of the cochlea, allowing for frequency-specific stimulation. These devices can be placed with 1 to 2 hours of surgery with relatively limited risk. Activation reliably provides sound awareness and speech understanding, thereby improving spoken language development and educational opportunities for children and communication, socialization, and (re)employment opportunities for adults. These benefits result in very favorable outcomes for cost-utility and quality of life. Future areas of investigation are focused on broadening indications, combining these devices with conventional acoustic hearing devices, totally implantable technology, and newer stimulation paradigms. Creating awareness of these devices for the general public is also seriously needed.

OSSEOINTEGRATED DEVICES

Overview

Traditional bone conduction hearing aids indirectly connect to the bony skull via the unbroken skin (105). A bone-anchored hearing system (or osteoconductive implant, generally termed the bone-anchored hearing appliance—BAHA), on the other hand, connects directly to the skull via a percutaneous attachment. Thus, the connection to the transmitting medium is provided in a much more direct fashion (106). This design allows to overcome many limitations of conventional bone conduction hearing aids. However, the abutment requires surgical placement, and while the surgery itself has evolved into a relatively straightforward procedure, minor postoperative skin complications are common (107).

Principles of Bone Conduction

Bone, like air, can conduct sound information mainly encoded via controlled oscillations. In a normal hearing person, the ear receives sound signals via air conduction mechanisms through the external and middle ears. Specifically, the tympanic membrane, the ossicles, and the stapes footplate act as an amplifier to ultimately result in peri- and endolymph oscillations of the inner ear. However, the fluid spaces of the cochlea can also receive sound information transmitted directly through vibrations of the skull. This mechanism bypasses the entire conductive apparatus of the ear (Fig. 163.9).

For patients with otherwise not correctable conductive hearing loss, a bone anchored hearing system provides a means for auditory rehabilitation. Such patients include children or adults with atretic ears, patients after failed ossiculoplasty, chronic suppurative otorrhea, or with otherwise not manageable conductive issues (106,108,109).

The other main indication for bone anchored hearing systems includes patients with unilateral deafness (110,111). Similar to the traditional indication for conductive or mixed losses, the sound signal is transferred via the skull. Due to the high tissue density of the skull, the device will always activate both cochleas. Thus, in single-sided

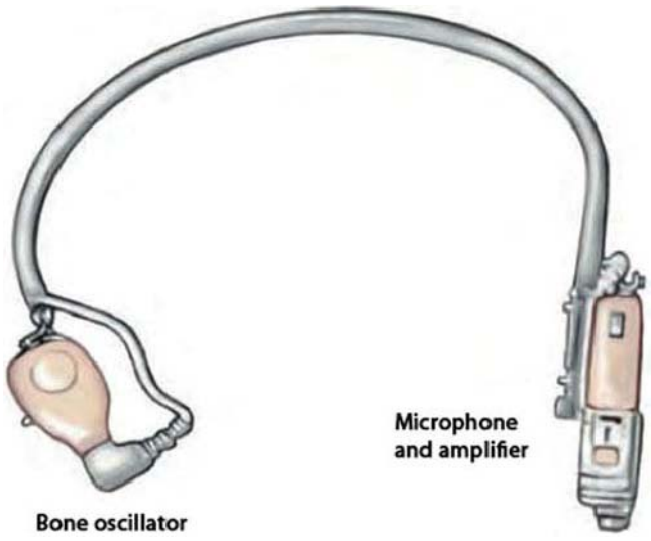

Figure 163.9 Illustration of a bone conduction hearing aid with contralateral routing of the sound signal (CROS).

deafness (SSD) candidates, the implant will help to transfer the signal through the skull to the contralateral ear. This eliminates the head shadow effect of binaural hearing. The patient will perceive spatial hearing even though only one cochlea is activated. However, the patient will not have access to the other physiologic effects of binaural hearing, as such the squelch and the binaural summation effect. They also will not be able to localize sound. Thus, the perceived hearing in these cases is pseudospatial (110).

Following this principle, binaural cochlear stimulation should be considered prior to implantation even with the traditional indication for conductive or mixed hearing losses. Specifically, unwanted contralateral stimulation might in some cases be perceived as detrimental. Adequate preoperative planning including proper estimation of the cochlear reserve and the required gain are essential.

Biologic Aspects

The main advantage of a bone-anchored hearing system is that it bypasses the conductive element of a hearing loss through direct bone conduction. Thus, it only has to provide amplification for the sensorineural component. However, in order to be able to provide adequate amplification, a minimal cochlear reserve must be met. With currently available devices, a bone conduction threshold of 65-dB HL or better should be present. Therefore, conductive or mixed hearing losses with adequate cochlear reserve and an air–bone gap or more than 30-dB HL measured at 500, 1,000, 2,000, and 4,000 Hz are among the proper indications.

With modern titanium implants, sectional imaging technologies such as CT and MRI remain feasible with the implant left *in situ*. Specifically, pure titanium produces little to no artifact on either imaging modality. Naturally, the audio processor (AP) needs to be removed prior to an MRI.

Current Device Technology

A bone anchored hearing system is typically a three-component medical device for the treatment of hearing loss. Currently available systems are manufactured by Cochlear Ltd (BAHA system, NSW, Australia) and Oticon Medical (Ponto System, Askim, Sweden). The system consists of a sound processor, an abutment, and a titanium implant (Fig. 163.10). The sound processor picks up the sound signal through a microphone. The signal is then amplified and converted into controlled oscillations. The abutment, or connector, links the sound processor and the osseointegrated titanium implant. The titanium implant is a small fixture surgically placed behind the ear, which transfers the sound information to the bony skull. As mentioned previously, the implant requires proper osseous integration to avoid failure of the system.

There are several sound processors depending on the severity and the type of hearing loss. As such, each device has different minimum bone conduction thresholds (measured at pure tone averages: 45-dB HL for the BAHA Divino, BP100 (or the Ponto/Ponto Pro); 55-dB HL for the larger Intenso (or the Ponto Pro Power); 65-dB HL for the body worn BAHA Cordelle II) to compensate for various levels of sensorineural components.

Candidacy for Bone Anchored Hearing Systems

A bone anchored hearing system is recommended for three types of hearing loss:

1. Conductive hearing loss
2. Mixed hearing loss
3. SSD

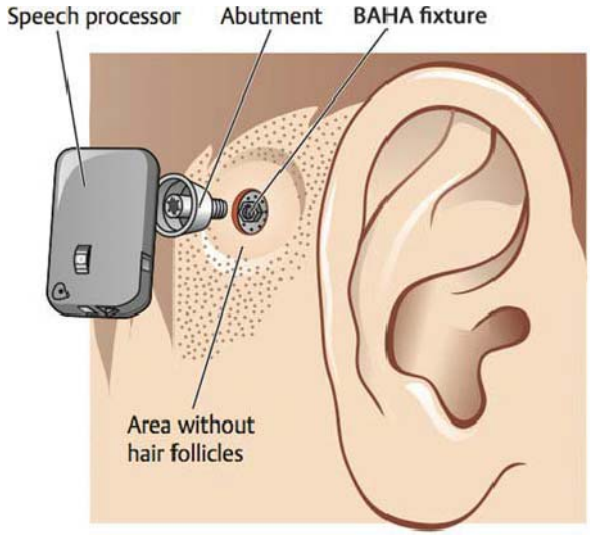

Figure 163.10 BAHA system consisting of the implant (*screw*), the abutment, and the AP.

Conductive or Mixed Hearing Losses

Various causes of conductive or mixed hearing losses have been described. They can be either congenital or acquired and the medical or surgical management mainly depends on the cause and other patient-related factors. If hearing restorative procedures are not feasible, conventional bone conduction hearing aids are the treatment of choice. These devices are available in various designs and typically include either a spring or soft headband or are included in the frame of a pair of glasses. However, traditional bone conduction hearing aids have many disadvantages. These include inconsistent coupling and resulting poor sound quality, associated reduced clarity and volume, discomfort from constant external pressure applied to the skin, poor aesthetics, and difficult placement.

A bone anchored hearing system, on the other hand, offers significantly better sound quality as the sound is transferred directly to the bone. Thus, both sound clarity and volume are preserved. It works without the application of pressure onto the skin, avoiding discomfort, headaches, and soreness typically associated with conventional bone conductors. Thus, a bone anchored hearing system offers wearing comfort, but it requires surgical placement of the implant including the percutaneous abutment.

Criteria for conductive or mixed hearing losses (for ear-level sound processors such as the BAHA Divino or Intenso) are as follows:

- A minimum average bone conduction threshold of 45-dB HL (measured at 0.5, 1, 2 and 3 kHz) or 55-dB HL depending on the sound processor output
- For bilateral fitting, symmetric bone conduction thresholds are recommended (i.e., there is less than a 10-dB HL difference of the PTAs [frequencies 0.5, 1, 2, and 3 kHz] or less than 15-dB HL at individual frequencies).
- The BAHA Cordelle II body worn device is recommended for severe mixed hearing losses, but the average bone conduction thresholds of the implanted ear should be less than 65-dB HL (PTA 0.5, 1, 2, and 3 kHz).

Single-Sided Deafness

In the US alone, over 60,000 people per year suffer from SSD. The causes are multiple and include viral infections and subsequent sudden sensorineural hearing loss, Meniere disease, temporal bone fractures, and vestibular schwannomas. Multiple other causes have been described, some of them being congenital in nature. Many affected individuals learn to cope with this disability but are left without an adequate hearing solution. Previous management algorithms included a CROS (contralateral routing of signals) hearing device. These devices, however, are quite limited in terms of performance and user comfort.

A bone anchored hearing system provides an alternative treatment option for this population. As detailed above, the device transfers the acoustic information through the dense skull to the contralateral cochlea. Thus, it helps to generate an impression of binaural hearing, without actually providing the physiologic effects consistent with binaural signal processing. The head shadow effect is the sole exception, but elimination of this alone will account for the subjective benefit. Compared to CROS hearing aid, the BAHA features no occlusion effect, no need for a cable connection to transmit the signal, and overall improved sound quality through direct contact and sound transmission with the skull.

Criteria for unilateral sensorineural hearing and loss/SSD (for ear-level sound processors such as the BAHA Divino, Intenso, Ponto, or Ponto Pro) are as follows:

- Profound hearing loss in the implanted ear (Some candidates will have residual hearing, but these remnants should be nonfunctional in terms of speech understanding and pure tone perception.)
- Hearing in the contralateral ear is better than or equal to 20-dB HL (measured at 0.5, 1, 2, and 3 kHz).

Pediatric Population

The sound processor of the bone anchored hearing system can be fitted to infants and children in need for amplification via bone conduction (112). The indications for a bone-anchored hearing system in children are generally the same as for adults, except that in the US, only children aged five and older are cleared by the FDA for implantation. The main reason for this is the often-insufficient thickness of the bony skull, making proper osseointegration impossible. Of note, the device's implant fixture comes in two sizes (lengths), 3 and 4 mm. Younger children may be fitted with a bone anchored hearing system using the Softband (113,114).

Surgery for Bone Anchored Hearing Systems

The implant site is generally 50 to 55 mm from the ear canal and horizontally in line with the top of the pinna (Fig. 163.11). A small amount of methylene blue dye can be used to highlight the implant site through the intact skin. Various types of skin incisions can be used. It seems, however, that a straight vertical incision has been established as the most commonly used access (115). Then, the subcutaneous tissue layers are reduced, depending on the required final thickness. Then, the periosteal layer is removed from the previously marked bony implant site, and the guide drill is used to assess the bony thickness. First, a 3-mm hole perpendicular to the skull surface is drilled followed by a 4-mm one (typically with ~ 2,000 rpm, Fig. 163.12). The 4-mm-depth drill is used after drilling with the 3-mm burr estimating there is sufficient residual cortical bone for the longer drill bit. Many children and some adults will have limited skull thickness permitting a 3-mm-long implant only. Once the adequate depth has been determined, the hole is widened using a countersink drill.

Then, the titanium implant is drilled into the previously created hole with a torque controlled drill at very low

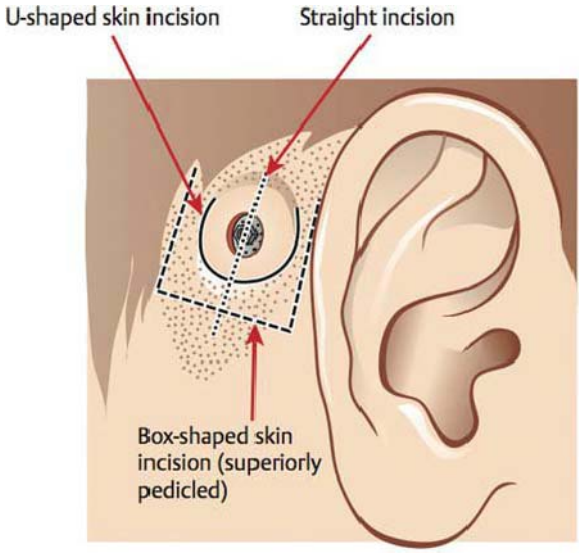

Figure 163.11 Skin incision options for placement of a BAHA. The straight incision has emerged as the preferred option used in clinical practice today.

speed. The threads of the implant will seat into the surrounding bone. For compact cortical bone, 40 to 50 Ncm of torque is typically used. Less torque is used for irradiated bone or in children. Then, the skin is closed around the abutment and the thickness of the surrounding soft tissues should be reassessed.

A healing cap is commonly placed onto the abutment, and the skin is compressed lightly using antibiotic gauze strips. The patient will follow in about 1 week to check the wound and the dressing is changed at that time. Also, the patient and his family members are carefully instructed on how to clean the abutment with its surrounding skin. The sound processor is loaded about 12 weeks postoperatively (116).

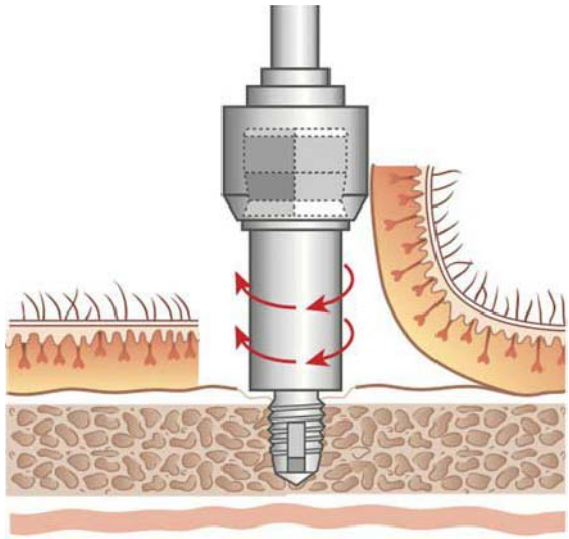

Figure 163.12 Placement of the implant into the skull. First, the thickness of the skull has to be assessed via 3- and 4-mm guide drills. Then, the site for the implant is created by enlarging the initial hole. The implant is then threaded using a torque sensitive drill.

Complications Associated with Bone Anchored Hearing Systems

The most frequently encountered complication associated with osseointegrated implants is a soft tissue reaction at the percutaneous implant site causing local infection, moisture, skin necrosis, or overgrowing over the abutment (117). Soft tissue reactions with percutaneous implants can be prevented via extensive intraoperative soft tissue reduction. Also, the skin can be tacked down to the periosteal layer to immobilize this region. Complications other than adverse skin reactions are rare. Osseointegration failure, though uncommon, is the second most common complication of this procedure.

Expected Outcomes

Overall, the bone anchored hearing system seems to offer patients with a bone conduction pure tone average of less than 45 dB a high degree of hearing rehabilitation and excellent patient satisfaction (118). This has been well documented by several clinical studies and trials. Once the initial healing phase of the skin-abutment interface has been completed, the device is reliable and the maintenance is generally low. The results for SSD have also been well documented (119). Overall, the authors encourage a trial with a bone anchored hearing system mounted in a headband so the patient can decide on whether or not proceed with implantation. As mentioned previously, a bone anchored hearing system will not provide true binaural hearing with this indication. Instead it will eliminate the head shadow effect and thus create a sensation of spatial hearing (110).

New Device Developments

The main issues associated with bone anchored hearing systems pertain to skin complications due to the percutaneous attachment. To eliminate this problem, several groups have helped to develop transcutaneous or other alternative solutions. These efforts, such as the Alpha 1 hearing system (Sophono, Boulder, CO, USA), have been approved in Europe but are currently under investigation with the FDA. Also, other efforts focus on application of the acoustic information via the jaw. Specifically, a dental appliance featuring a transducer can apply controlled oscillations to the maxilla or mandible for similar indications as conventional bone conduction devices (SoundBite, Sonitus Medical Inc., San Mateo, CA, USA).

ACTIVE MIDDLE EAR IMPLANTS

Overview

Conventional hearing aids provide amplification via the regular sound conduction apparatus of the ear. Active MEIs, on the other hand, convert acoustic information into controlled oscillations that can be transmitted either to

the ossicular chain or directly to the inner ear fluid spaces (120). This method has several potential advantages over conventional hearing aids. The primary and most commonly described advantage of active MEIs is that the external auditory meatus can remain free of the actual device or an earmold. This occlusion effect is perceived as bothersome by many individuals, and some patients develop chronic otitis externa from the earmold. Acoustic distortions at the level of the tympanic membrane especially with high sound intensity levels and subsequent sound quality issues have also been described as common issues with conventional amplification. Also, many hearing aids struggle with some hearing configurations such as steeply sloping losses. In these cases, direct drive of the ossicular chain provides additional advantages over conventional technology.

New indications include conductive or mixed hearing losses (currently not FDA approved and under clinical investigation in the US). In these cases, the oscillating part of the device is placed on ossicular remnants, the round window, or other vibrating parts providing access to the fluid spaces of the inner ear (121). With these indications, active MEIs are an alternative mainly to bone anchored hearing system. In contrast to the BAHA, for example, active MEIs do not feature a percutaneous connection requiring permanent maintenance but instead use a transcutaneous link for information and energy transfer. Furthermore, active MEIs are not indicated for SSD since they do not use the bony skull for sound transmission to the contralateral ear.

Historical Aspects

Early attempts to actively stimulate the middle ear date back to the early 20th century. More concrete attempts were described in the 1970s and 1980s where piezoelectric systems were used for various hearing loss configurations. These attempts included both animal work and human implantations. Also, electromagnetic devices have been studied in both the animal model and later in humans in the 1980s. Each investigation established the feasibility of active stimulation of the conductive apparatus and the potential benefit of active stimulation to patients (122).

Most systems today feature semi-implantable technology similar to that used in modern cochlear implants. A transcutaneous link provides power and data to the internally placed demodulator and stimulating element. More recent efforts have focused on fully implantable technology with various solutions for sound sensors and implantable microphones. The first fully implantable system was the TICA (Implex AG, Germany), which featured a microphone in the subcutaneous tissue of the external auditory canal (123). It was first implanted in 1999 and feedback from the tympanic membrane required removal of parts of the ossicular chain. Due to technical difficulties, the device was eventually removed from the market.

The Vibrant Soundbridge (Symphonix, Inc., now Vibrant MED-EL, Innsbruck, Austria) was first implanted in 1996. The device has been FDA approved since 2000. Specifically, it has had FDA and CE approval for the treatment of sensorineural hearing loss and has CE approval in European countries for conductive and mixed hearing losses (121,124–126). It is currently under clinical investigation in the US for these indications.

Several issues make current fully implantable technology problematic. For one, the life of a rechargeable battery remains limited. However, new fully implantable rechargeable batteries may not demonstrate any loss of capacity for several thousand recharge cycles or about 10 years. The other main issue with fully implantable technology concerns the microphone. As detailed below, acquisition of the sound signal with fully implantable technology still underlies various inconsistencies and problems (37).

Despite the main technologic advances, active MEIs remain small in numbers when compared to conventional hearing aids or even cochlear implants. The main reasons for this seem to be financial in nature and the fact that all devices require surgical placement. Newer indications and larger patient numbers might help to improve documentation efforts and thus help provide payers and patients with better and more accurate performance and quality of life data.

Principles of Direct Ossicular or Cochlear Stimulation

Conventional hearing aids receive acoustic energy through a microphone and subsequently process and amplify the signal in a speech processor. This is then transmitted through a speaker (termed receiver in hearing aid terminology) and delivered into the external auditory canal (via a sound tube and/or an earmold) to stimulate the tympanic membrane. Active MEIs, in contrast, convert the sound signal into electrical energy and then into mechanical oscillations to amplify vibratory structures of the middle (or inner) ear.

The critical component of all MEIs is the transducer, which enables the device to deliver the sound information as a vibratory signal. This transducer can be either in direct or indirect contact with the intended structure. Two basic types of transducer technologies have been described: piezoelectric and electromagnetic (120,127). Piezoelectric devices use an amplifier featuring a piezoelectric crystal to generate oscillations. Piezoelectric materials (mostly ceramics) are dielectric materials with coupled electrical and mechanical properties. Applying a voltage across a piezoelectric rod, for example, causes it to bend or lengthen, in a precise and predictable voltage-dependent fashion. Within the implant, the sound signal acquired by a microphone is converted by the signal processor and then sent to the piezoelectric rod. As this rod vibrates in response to the converted auditory signal, it comes in direct contact with

the intended structure of the sound-conducting apparatus (typically the incus or stapes). A critical feature of implants that use a piezoelectric transducer is the direct contact between the piezoelectric unit and the ossicles or the inner ear. The advantage of this type of transducer is its ability to deliver more distortion-free amplification directly to the ossicular chain and the low energy consumption.

Implantable middle ear hearing aids may also incorporate an electro-(ferro)magnetic transducer. These transducers generate a magnetic field, which then generates oscillations in a ferromagnetic medium that is nearby. Sound received from a microphone is converted by the signal processor, processed, and sent to the electromagnetic transducer. Both ferromagnetic units featuring either direct or indirect contact with the ossicular chain are available. Devices directly in contact with the target structure deliver oscillations as a result of direct attachment. Ferromagnetic transducers featuring indirect contact with the ossicular chain, on the other hand, rely on electromagnetic transmission to a ferromagnetic target unit, which is then attached to the ossicles.

The properties of the transmitting coil can influence the properties of the oscillating elements. As such, devices of 50 mg or more can influence ossicular motion and thus cause a conductive hearing loss, first affecting the high frequencies. The main downside of electromagnetic devices is the higher energy consumption when compared to piezoelectric technology.

Ossicular Attachment

Electromagnetic or piezoelectric transducers of active middle era implants are attached to various locations along the ossicular chain or the inner ear windows. The Vibrant Soundbridge attaches to the long process of the incus (Figs. 163.13 and 163.14). However, the floating mass transducer (FMT) assumes a position parallel to the stapes. Thus, the electromagnetic energy is applied in a direction mimicking the natural motion of the stapes.

The MAXUM System (Ototronix, LLC, approved by the FDA since 2009) attaches to the incudostapedial joint. It was previously approved as the SOUNDTEC Direct (Drive) Hearing System in 2001 but was ultimately withdrawn in 2004 and redesigned. The electromagnetic energy is thus applied directly to the ossicular chain in a similar fashion as with the Soundbridge. Piezoelectric systems directly attach to various portions of the ossicular chain. The Esteem system's driver provides oscillations directly to the head of the stapes (Fig. 163.15). In this system, the long process of the incus has to be removed to avoid acoustic feedback to the sensor acquiring sound information from the ossicular chain.

Various other device attachments are theoretically possible, and some have been realized in previous technology or in devices currently in clinical investigation. In this context, it seems worth mentioning that these alternate attachments include transducer placement in conjunction with passive middle ear prostheses such as stapes pistons as well as partial or total ossicular replacement prostheses.

Figure 163.13 FMT of the Vibrant Soundbridge hearing system. The clip on the upper right-hand side attaches to the long process of the incus. In case of alternative placement sites such as the round window, this clip can be removed.

Direct Cochlear Fluid Stimulation

Stimulation paths other than via ossicular chain have been explored. The MEI transducers can be attached to the round window or oval window and directly stimulate the cochlea (Fig. 163.16). In case of a round window vibroplasty, the round window niche is drilled to accommodate the transducer, which is placed perpendicular to the round window. To improve coupling, a small piece of fascia is placed between the round window membrane and the transducer. An additional tissue such as fascia or perichondrium is

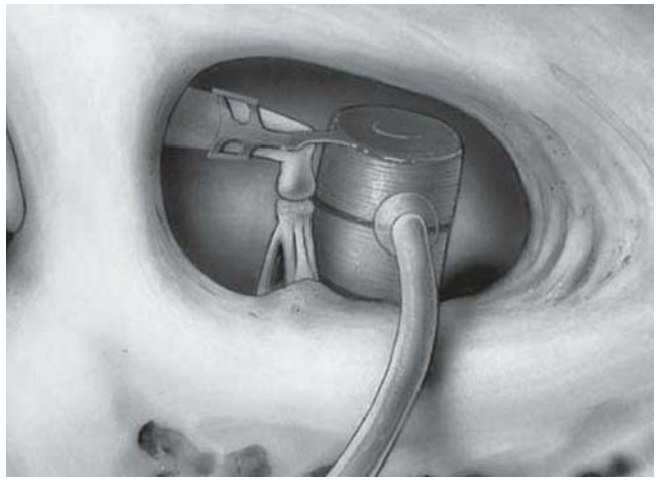

Figure 163.14 Traditional attachment of the Vibrant Soundbridge's FMT on the long process of the incus parallel to the stapes.

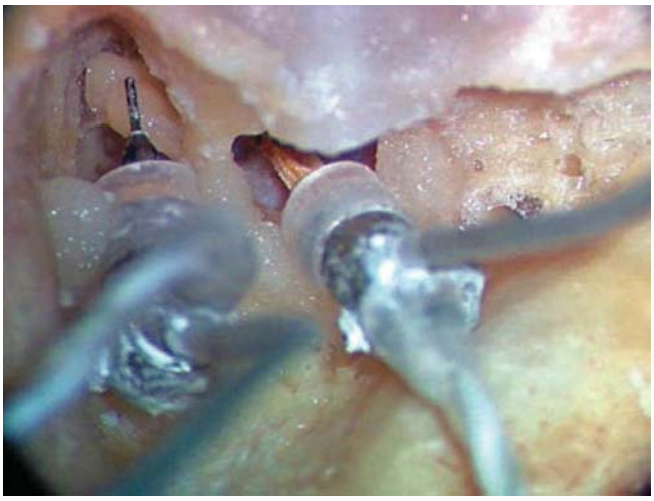

Figure 163.15 Intraoperative image (right ear) of the Envoy Esteem's transducer. The device on the left-hand side of the image depicts the transducer picking up the acoustic signal from the body of the incus. The transducer inserted through the facial recess stimulates the head of the stapes for signal delivery.

placed on the contralateral side of the transducer to secure the position.

Biologic Aspects

As with conventional hearing aids, implantable active MEIs underlie the general biologic limitations of the inner ear. Specifically, loss of inner hair cells with accompanying speech discrimination issues will limit the effectiveness of the device as much as this affects satisfaction with conventional hearing aids. As such, the devices mentioned below are mainly designed to overcome mild-to-moderate sensorineural hearing impairments with generally good discrimination abilities.

Tissue compatibility issues are theoretically possible with any implantable device. With the original attachment on the long process of the incus, device fixation is typically permanent, although cases of device issues due to failure of the attachment have been described. With new indications requiring fixation on the round window niche or other parts of the labyrinth, possible device relocation issues have been described. The biology of the underlying pathology can thus not be ignored. Specifically, eustachian tube dysfunction requiring radical tympanomastoidectomy will require special surgical considerations when placing an active MEI for aural rehabilitation. In such cases, closure of the external auditory canal has been suggested to remove the potential cause for postoperative problems. This can be performed in a separate procedure before the actual device is placed.

Other potential issues can arise with retrocochlear hearing loss. At this point, the authors recommend alternative management options for this type of hearing impairment especially when the prognosis is unclear and/or if speech perception is substantially impaired.

Figure 163.16 Alternate placement site of the Vibrant Soundbridge onto the round window membrane for direct cochlear stimulation.

Current Device Technology

Currently three FDA-approved active MEIs are available: the Vibrant Soundbridge (MED-EL, Innsbruck, Austria, formerly manufactured by Symphonix, Inc., initial FDA approval August 31, 2000, Fig. 163.17) (125), the fully implantable Esteem Implantable Hearing System (Envoy Medical Corp., St. Paul, MN, USA; FDA approval March 17, 2010) (128), and the MAXUM System (Ototronix, LLC, Houston, TX, USA; formerly the Direct Drive Hearing System, DDHS, SOUNDTEC, Inc., Oklahoma City, OK, USA, most recent FDA approval October 2009). All three systems are approved devices for moderate-to-severe sensorineural hearing loss. Other indications including use for conductive or mixed losses are currently under investigation in the US and/or approved in Europe. The Vibrant Soundbridge and

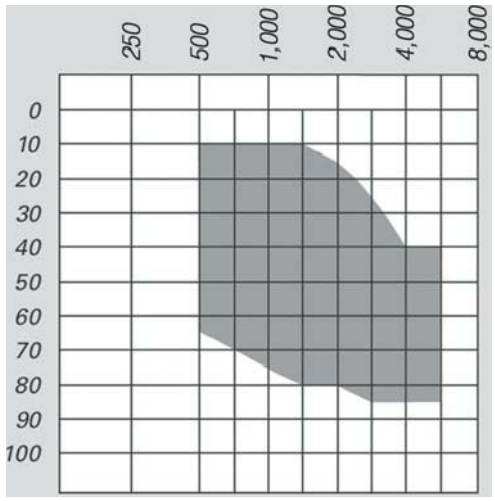

Figure 163.17 Typical audiogram template for active MEIs (in this case the Vibrant Soundbridge). Most devices are indicated with a moderate-to-severe sensorineural hearing loss with intact discrimination. Thus, the underlying biology of the sensorineural hearing loss should be carefully evaluated.

the DDHS systems are semi-implantable solutions, and the Envoy system features completely implantable technology.

Various other devices are currently under clinical investigation (Otologics Carina fully implantable system; featuring a postauricular implantable microphone and a middle ear transducer, Otologics LLC, Boulder, CO, USA).

The Vibrant Soundbridge consists of an externally worn AP and an implantable vibrating ossicular prosthesis. Similar to a cochlear implant receiver/stimulator, the latter consists of an internal coil, a magnet to secure the external components over the implant, a demodulator, a conductive link, and a so-called FMT (129,130). The FMT is the active portion of the implant and features a brace for attachment on the long process of the incus (Fig. 163.13). Several revisions of the AP have been available over the years this device has been available. The current technology uses digital sound processing as well as an external microphone and power source as part of the AP. To facilitate proper osseous integration, the device should not be activated for 8 weeks after surgery.

The MAXUM System features three components: the implant, the earmold/coil assembly (ECA), and the external amplification system or sound processor. A permanently implanted magnet is attached to the incudostapedial joint. Similar to the principle of the Vibrant Soundbridge, it provides controlled oscillations to the ossicular chain via an electromagnetic process. However, instead of a cable connection to an implantable demodulator, the implant receives its energy via the external auditory canal. Specifically, the ECA component of the device creates an alternating electromagnetic field together with the magnetic implant. The ECA therefore consists of an electromagnetic coil and an earmold/coil assembly casing. This casing is customized to the patient's external auditory canal dimensions obtained from an earmold impression. This mold can be extensively vented to minimize the external auditory canal occlusion effect. The sound processor of this system rests over the patient's external auditory canal, and it serves to convert the sound pressure into electrical signals. It consists of a microphone, a preamplifier, and a power amplifier, which has been designed to preserve battery life.

The fully implantable Esteem Implantable Hearing System features piezoelectric technology. It consists of three implantable components, external testing/programming instruments, and system accessories. Piezoelectric transducers are used to sense the acoustic sound signal from the ossicular chain and to directly drive the stapes (Fig. 163.15). The implant consists of a titanium-encased sound processor, a rechargeable battery, and two piezoelectric transducers. The sensor transducer picks up sound information from the body of the incus. It is fixated in this location with glass-ionomer cement. Similarly, the driver transducer is implanted through a facial recess approach and fixated to the head of the stapes. In order to avoid acoustic feedback via the ossicular chain, the distal tip of the long incus process has to be removed, typically via a laser. The device can be activated 6 weeks after implantation.

Candidacy for Active Middle Ear Implants

As an alternative for conventional hearing aids, active MEIs are primarily an alternative treatment option for hearing aid candidates. As such, the classical indication is mild-to-moderate sensorineural hearing loss with intact speech discrimination abilities (Fig. 163.18). Some device

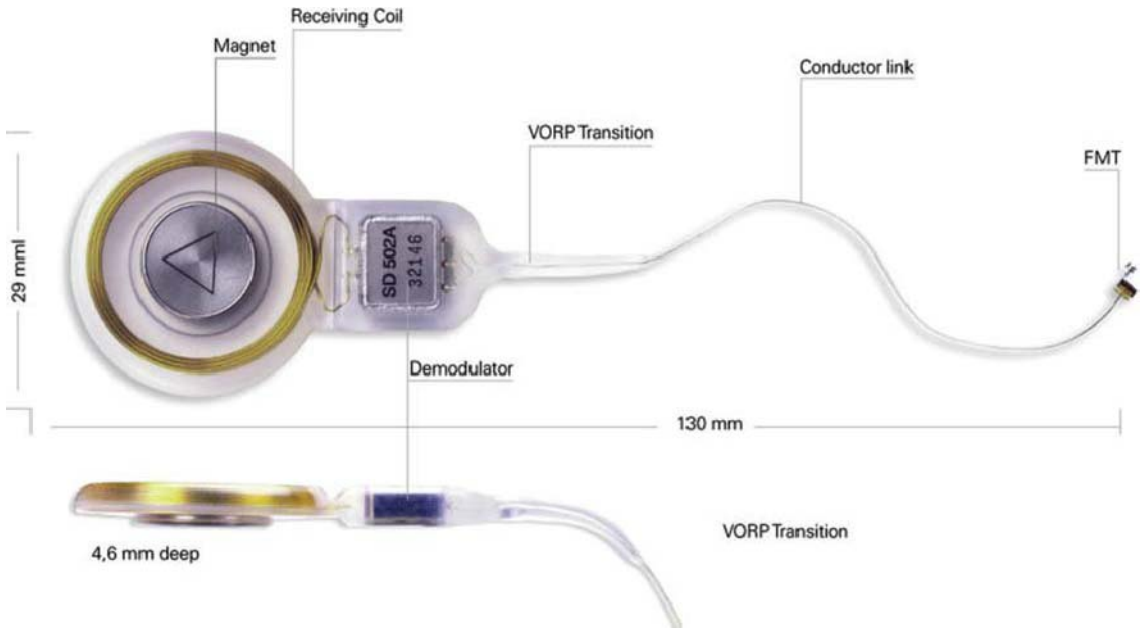

Figure 163.18 Image of the Vibrant Soundbridge implant consisting of the demodulator, the conductor link, as well as the FMT (floating mass transducer). This implant generates controlled oscillations of the ossicular chain (or the cochlear fluids) via a direct electromagnetic link.

indications include severe hearing losses. However, the clinician should keep the underlying biology of sensorineural hearing loss with potential loss of discrimination in mind. Also, indication criteria for cochlear implants continue to evolve, and many individuals with severe and some with moderate-to-severe losses are now considered cochlear implant candidates.

Many retrocochlear hearing deficits often demonstrate more severe speech discrimination problems than what would be expected from the pure tone audiogram. Thus, most manufacturers advocate a thorough trial with conventional hearing aids before proceeding with an active MEI when sensorineural hearing loss is being treated. The classic patient is an unsatisfied hearing aid candidate. Reasons for this dissatisfaction may include chronic external auditory canal issues from wearing the earmold or a bothersome occlusion effect.

Newer indications for active MEIs include conductive and mixed hearing losses. Both often require alternative attachment sites of the electromagnetic or piezoelectric transducer. For example, placement of the Vibrant Soundbridge on or near the round window has been thoroughly investigated. This site has been approved for clinical use in Europe and is currently under clinical investigation by the FDA. It allows bypassing both the external and middle ear. Thus, indication criteria include mixed or conductive losses from various causes mostly including chronic otitis media with previously failed ossiculoplasties. In case of a radical tympanomastoid cavity, it is important to provide adequate coverage of the device's components and wires. Many authors thus advocate closure of the external auditory canal either in a staged fashion or in a single operation.

Alternative attachment sites also provide other interesting applications: Atresia of the external auditory canal, for example, seems to be a perfect fit for active MEIs. Typical results after atresiaplasty are more often than not dissatisfactory for both patients as well as the clinician. Also, surgeries often have to be coordinated with reconstructive measures of the auricle. Specifically, atresiaplasty cannot precede functional reconstructive measures. A BAHA headband is often times the only option in early childhood (131). With adequate bone thickness, typically reached around age 7, an implanted BAHA might be considered. However, even in this scenario directional hearing may be compromised due to the BAHA's capacity to stimulate both inner ears simultaneously. Also, the BAHA features a percutaneous attachment requiring extensive skin care and the potential for complications.

Thus, active MEIs could provide a reasonable alternative. Previous clinical investigations have found that the procedure's scarring is minimal and will therefore not interfere with later reconstructive measures (132). As such, placement of the device may be performed at an earlier age before cosmetic reconstructive procedures are being considered. As a downside, some atretic ears feature virtually no landmarks, no pneumatization, a very shallow middle ear space, and an aberrant position of the facial nerve. The latter can take a very anterior course in its mastoid segment making positioning of the FMT within the round window problematic. In such cases, surgery has to be carefully weighted against other options. Also, successful placement of the active portion of the device on the oval window has been described (133).

In summary, sensorineural hearing loss remains the main (and often only FDA approved) indication for active MEIs. Newer sites of attachment are very promising and have been approved in Europe. Clinical algorithms may have to be established, and more data from controlled clinical trials should enhance our understanding of direct cochlear stimulation.

Surgery for Active Middle Ear Implants

Every active MEI requires surgical placement of the transducer on the ossicular chain or an alternate site such as the round window. Except for electromagnetic devices featuring indirect transducer technology such as the MAXUM System, all other devices require implantation of other components as well. These include the demodulator and the cable connection with the transducer. Fully implantable systems also consist of a rechargeable battery, a sound processor, and a sensor device (either a subcutaneous microphone or a piezoelectric transducer as a sensor). In such cases, the surgical procedure typically includes a mastoidectomy and a (large) facial recess to access all middle ear structures necessary.

Additional hardware such as the demodulator requires a bony recess in the postauricular area. Skin incisions are adapted to the requirements of the device. With current technology, a standard postauricular incision is typically sufficient since it provides standard access to the mastoid and it allows proper placement of other device components.

Postimplantation (Re)habilitation and Fitting

After implantation, a healing period of several weeks or months is required before the device can be activated. The main underlying reason for this is proper ossicular integration of the active portion of the implant. Also, these intervals vary greatly among available devices. In any case, proper postoperative surgical follow-up should be employed. Then, device fitting is performed according to the manufacturer's specifications. Fitting software and amplification strategies are very similar to conventional hearing aids. Thus, a dispensing audiologist familiar with fitting conventional amplification will find the process intuitive.

Care must be taken not to overstimulate the cochlea. This has been reported mainly for alternative indications for conductive or mixed hearing losses. In these cases, the device gain is often too great and some patients experience

a humming sound or a low-frequency noise floor. In our experience, this effect is a temporary one which did not require further surgical or audiologic action.

Proper follow-up should include annual visits with the surgeon to check for potential complications such as device extrusion, coupling issues mainly evident as performance loss of the implant, or other infectious issues. In cases in which the external auditory canal has been closed, careful follow-up should include assessment of squamous ingrowth and iatrogenic cholesteatoma formation.

Audiologic follow-up should be performed more frequently to adjust the device's fitting parameters to the patient's hearing loss. Potential progressive losses should undergo frequent testing and device adaptations. With progressive sensorineural losses, the clinician should reevaluate the patient's speech discrimination abilities to reassess suitability for the device. The authors have encountered patients who eventually required cochlear implantation due to a previously undetected progressive loss of hearing.

Expected Outcomes

Several clinical trials have now documented the beneficial effects of active MEI (125,126,134). The published data also include the benefits to the patients hearing-related quality of life (135). Overall, it appears that active MEIs provide the patients with improved sound quality and wearing comfort while offering objective hearing results equal to optimally fit conventional hearing aids. Thus, the underlying biology of the inner ear should be carefully assessed prior to implantation.

For newer indications not yet fully FDA approved, active MEIs offer an alternative treatment option. Specifically, patients with otherwise non-correctable conductive hearing loss components can be successfully rehabilitated using the Vibrant Soundbridge. The transducer (FMT in case of this device) can be placed on the round window or on ossicular remnants. Theoretically, this principle applies to other MEIs as well as long as the transducer allows proper fixation and transmission of sound energy. The Soundbridge has been approved for these types of indications in some countries outside the US. Since the device has been designed to overcome hearing loss, normal inner ear function with device placement onto the round window can sometimes be problematic. Often, the amplification has to be reduced to a minimum to avoid overstimulation. Some patients will report a humming in the initial phase after fitting. Naturally, with mixed-type hearing losses, this is less of an issue.

The results with round window vibroplasty continue to evolve. Clinical data from Europe demonstrates the hearing and quality of life benefit (121,136). For some less common indications such as for children and adults with atretic ears, the device also seems to provide a very reasonable alternative to conventional methods such as atresiaplasty or a BAHA (137,138). Compared to the latter, round window vibroplasty might offer the advantage of true binaural hearing since the BAHA provides bilateral cochlear stimulation through the skull (110).

Complications

Since active MEIs require surgical placement, they are subject to potential complications. These are essentially what would be expected from transmastoid procedures including facial recess drilling. Specifically, most devices require a large recess. Thus, it is not surprising that chorda tympani injury has been frequently reported in clinical trials assessing active MEIs. Other surgery-related complications include skin breakdown and postoperative infection of the device and subsequent extrusion, as well as improper device placement and inadequate hearing benefit.

Device-related complications include inadvertent activation with various electromagnetic fields such as a microwave oven or the like. These events can cause various harmless but annoying auditory perceptions. Device failure, on the other hand, although rare, has been described. Failure modes are similar to cochlear implantation mainly due to failures of the hermetic seal of the demodulator. However, other components of the device could potentially be subject to failure as well.

AUDITORY CNS IMPLANTS

Overview

The ABI is a device designed to convert environmental sound into electrical impulses that are delivered along a multiple electrode array situated in close proximity to the cochlear nucleus in the brainstem. In a manner similar to the cochlear nerve, the cochlear nucleus maintains some degree of tonotopic arrangement; thus, application of discrete electrical stimulation along certain stations within the lateral recess of the fourth ventricle results in variably different, psychophysical frequency percepts. The ABI is indicated for patients in whom the cochlear nerve is absent or unavailable for stimulation bilaterally. Most commonly, patients with hearing loss secondary to neurofibromatosis type II with bilateral acoustic tumors have been the main group of patients implanted to date. Outcomes for these patients have been quite variable, but in most instances, patients gain significant sound awareness and enhanced lipreading from their devices. While open-set speech perception is unusual, occasionally individuals with ABIs can achieve such results. This section will discuss ABIs.

History

The first ABI was a single electrode device placed by William E. Hitselberger and William F. House in 1979 in Los Angeles, CA, following an acoustic neuroma removal in a patient with neurofibromatosis type II. This device provided some auditory awareness for the patient. Over the following years, with greater understanding of tonotopic

awareness and multichannel stimulation with cochlear implants, a multichannel ABI was developed. The initial devices were based on the House–3M cochlear implant speech processor. Ultimately, working with Cochlear Corporation and Huntington Medical Research Institute in Pasadena, a 21-electrode array on a silicone and Dacron carrier was developed. This array when combined with the Sprint speech processor comprised the Nucleus 24 ABI. The processor is a body-worn device (Sprint processor) that performs spectral analysis (SPeak), digital processing, stimulus encoding, and transmission of commands to the implant through an RF link. The US FDA approved the Nucleus 24 ABI (Cochlear Corp, Englewood, CO) for commercial usage in 2000 (139) (Fig. 163.19). Digisonic Corp (Laboratories MXM, France) and Med-EL Corp (Austria) also manufacture ABI devices today, but these are not available for use in the US today.

Principles of Electric Stimulation of the Auditory System and Coding Strategy

As the ABI was developed from the cochlear implant, the basic tenants of stimulation are similar (see Cochlear Implants). The tonotopic arrangement of the cochlear nucleus, however, is somewhat more complex and less accessible in some regions. For instance, cochlear nerve fibers transmitting low-frequency sounds project mainly to the ventral portion of the cochlear nucleus, while basal cochlear nerve fibers transmitting high-frequency sounds project to the dorsal portions of each nuclear subdivision (140). This organization is best defined in the dorsal cochlear nucleus, the most superficial and exposed part, where the axis of the tonotopic gradient is oriented parallel to the brainstem surface (141). Although this issue might be a theoretical advantage for electrical stimulation, significant ascending information is processed in the deepest part of the anterior ventral cochlear nucleus, which is almost unexposed within the lateral recess area. Thus, surface stimulation might not fully be able to access the functionally important regions and might explain, in part, the relatively poor performance achieved by patients when compared to the cochlear implant. With this in mind, the penetrating auditory brainstem implant was developed in an attempt to achieve better performance. This device attained lower thresholds for stimulation, increased pitch range, and high selectivity, but these properties unfortunately did not result in improved speech recognition (142).

Figure 163.19 Cochlear Corporation's Auditory Brainstem Implant System. The system features a flat electrode array with 21-electrode contacts. This array is positioned on the surface of the cochlear nucleus.

Indications

The primary indication for ABI is for patients with profound hearing loss and no available cochlear nerves to stimulate bilaterally. As the ABI device was originally designed for the purposes of helping patients with neurofibromatosis type II, this remains the most common indication and the only FDA-approved indication for use in the US today. There remain a number of other clinical scenarios that might be amenable to ABI, and these include congenital cochlear nerve aplasia, bilateral temporal bone fracture with cochlear nerve disruption, severe inner ear malformation, or dense ossification secondary to previous meningitis (143). In these cases, cochlear nerve integrity might be unclear, and a trial of cochlear implantation might be justified prior to undertaking an ABI operation (75).

Surgery

ABI placement is generally carried out through a posterior fossa craniotomy—either translabyrinthine or retrosigmoid. The distinct advantages of the translabyrinthine approach for ABI are (a) incision location that is more natural for receiver–stimulator placement, (b) a lack of cerebellar retraction, (c) direct line of site to the lateral recess of the 4th ventricle afforded by the presigmoid exposure, and (d) electrode path through the immobile temporal bone rather against the pulsatile cerebellar hemisphere. However, this approach can be limited in some cases by a high jugular bulb, making lower cranial nerve and recess visualization somewhat more tangential and difficult at times. Clearly, surgeons have effectively placed ABIs through both

approaches with acceptable results (144,145). In cases of neurofibromatosis type II, acoustic neuroma removal precedes device placement. Cranial nerve monitoring should include facial muscle electrodes, as well as palatal and trapezius electrodes to monitor cranial nerves 9, 10, and 11. ABR monitoring electrodes include a non-inverting electrode ("active," "positive") at the vertex of the head (Cz), the inverting ("reference," "negative") electrode placed in the region of the C7, and the ground electrode at the hairline at the back of the neck (Oz). Alternatives to this electrode montage also exist.

The receiver–stimulator should be placed in a region similar to the cochlear implant, in a subperiosteal pocket. Given the extent of periosteal dissection needed for exposing the temporal bone for the approach, intraosseous tie-down holes with suture fixation can be useful for immobilizing the device. The retaining magnet is left in the device for initial placement to help retain the headpiece during intraoperative electrophysiologic testing.

The lateral recess of the fourth ventricle (i.e., foramen of Luschka) is the target for device placement. Landmarks for identifying this recess include the 8th and 9th cranial nerve root entry zones at the superior and inferior boarders of the recess, respectively. The cerebellar flocculus lies on the posterior side of the recess, and the choroid plexus can usually be identified exiting the foramen. There can be veins overlying the recess opening and careful dissection is often needed to mobilize them without disruption. As the cochlear nucleus lies on the ventral surface of the foramen superiorly, the electrode contacts should face anteriorly–superiorly. The electrode array should be advanced until the proximal most electrodes on the array are just inside the opening. Teflon can be used to pack the recess to immobilize the array. Intraoperative monitoring of the implant evoked ABR is critical for appropriate device placement (Fig. 163.20). This procedure has been detailed previously (146). Examples of intraoperative view after electrode array placement and excellent electrophysiologic responses are shown in the figure. A postoperative CT also confirms array location (Fig. 163.21).

Complications

Surgical complications are mostly unusual from ABI surgery. In fact, most complications described in these patients result from the posterior fossa surgery indicated for removing the patient's acoustic neuroma rather than from the device placement. These might include bleeding, infection, facial nerve injury, loss of residual hearing, cerebrospinal fluid leakage, stroke, and death. Cerebrospinal fluid leakage along the electrode carrier is more common among ABI patients than typical acoustic tumor patients. These patients may also experience transient dysphonia and aspiration related to lower cranial nerve dysfunction. Inability to identify the lateral recess in large tumor or distorted anatomy cases can occur resulting in an inability to place the device. The electrode might become dislodged from the recess resulting in an absence of stimulation at activation.

During stimulation, it is common to experience nonauditory sensations that can be severe at times. In one series, 24% of individual electrodes could not be used because of nonauditory stimulation. Nonauditory sensations were usually described as tingling in the head or body. A smaller number of patients described dizziness or slight jittering of vision (147). Others symptoms can include choking, pain, vertigo, facial twitching, and potential changes in heart rate, blood pressure, and respiratory efforts. While these latter symptoms are very uncommon, special care is always taken during initial activation by having trained medical personal available for emergency resuscitation if needed (139,147–149).

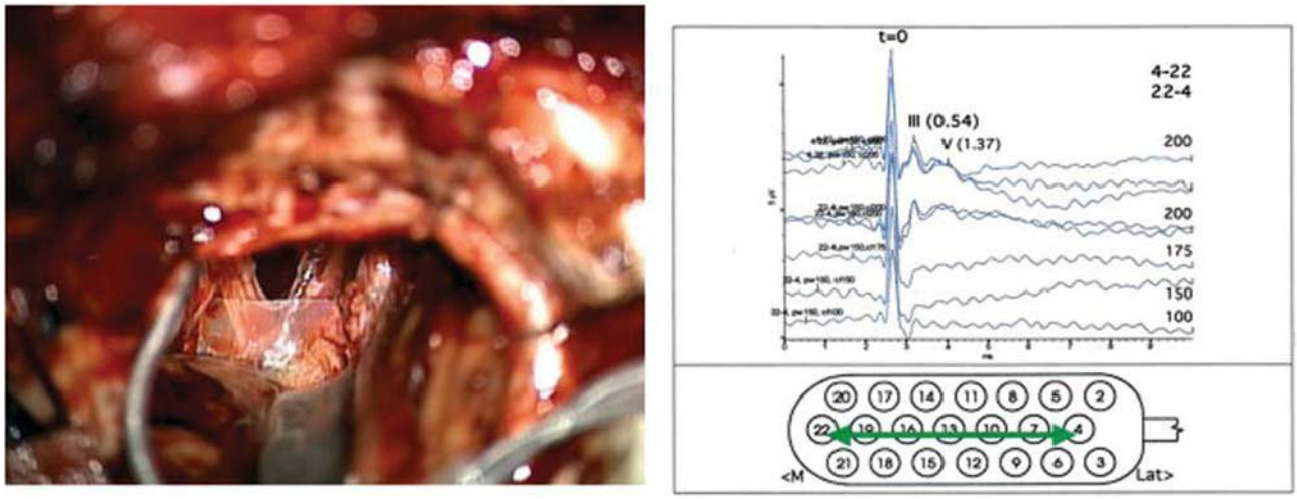

Figure 163.20 Intraoperative image (**left**) and electrically evoked auditory brainstem response (E-ABR) demonstrating proper placement of an ABR. The recording example shows evoked potentials when stimulating across the array (demonstrated below).

Figure 163.21 Axial head CT shows the expected postoperative appearance after placement of an ABI into the left lateral recess.

Outcomes

In general, outcomes from ABI can be described in terms of sound detection and speech perception abilities using closed- and open-set test materials with and without the addition of lipreading. In a recent review of 86 neurofibromatosis type II patients implanted with ABIs, 13 did not respond to stimulation and 1 was explanted. Of the 60 patients with available 6-month data, mean open-set speech perception scores (CUNY sentences) using the implant alone, vision alone, and both the implant and vision on CUNY sentence were less than 10%, 30%, and nearly 55% correct. However, there was a wide range of auditory abilities with some patients obtaining combined vision and sound scores of greater than 90% correct (148). Thus, in these patients, the ABI is an excellent enhancement to lipreading. For individuals that have known only spoken language throughout their entire life, this connection to the speaking world is significant, and the importance of this communication enhancement should not be underestimated.

More recently, Colletti et al. (150) in Verona, Italy, have placed ABIs in patients without neurofibromatosis type II. These non-tumor patients have had a variety of etiologies including labyrinthine ossification, cochlear nerve aplasia, temporal bone fractures, and severe inner ear malformations (150). While the results have been quite variable, some patients in this group have been able to obtain significant open-set speech perception abilities using audition alone. While these results remain to be confirmed, this report suggests that patients without neurofibromatosis type II might be better candidates for ABI. Further work is needed in this area.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Benjamin Wei, MD, PhD, for his assistance preparing this manuscript. Also, we would like to acknowledge Dr. Harold C. Pillbury, MD, for his continuous support and his leadership.

164 Hearing Aids and Assistive Listening Devices

Catherine V. Palmer *Barry E. Hirsch*

POPULATION

Hearing impairment is one of the most prevalent chronic disabilities in the United States. Approximately 34.25 million Americans have hearing impairments (1). The prevalence of hearing loss nearly doubled from 1965 to 1994, and the growth is predicted to continue (2). In the aging population, hearing loss is prevalent in nearly two-thirds of those over the age of 70 in the United States (3); these estimates are even higher in those with cognitive impairment such as dementia (4). Risk factors for hearing loss trend toward poor socioeconomic status, men more than women, and whites more than any other ethnicity (5). Hearing loss is associated with increased isolation (6) and functional and cognitive decline (6,7).

Hearing loss is most common in the aging population but also affects children; nearly 8% of those with permanent hearing loss are children (8). On any given day, 43% of elementary school students have a mild hearing loss (9). Congenital hearing loss affects 1 to 6 per 1,000 newborns (10). Most children with congenital hearing loss will be affected at birth and can potentially be identified by newborn hearing screening; however, some hearing losses may not be evident until later in childhood (11). Recent evidence suggests that hearing impairment in the teenage population is on the rise (12). The consequences of hearing impairment in both children and adults are detrimental to social involvement. Poor hearing leads to communication impairments and progressive social isolation that may impact overall health (13,14). Many of the health and social consequences of hearing loss can be mitigated with a comprehensive auditory (re)habilitation program of which hearing aids will be a part.

Individuals pursue hearing aids and assistive listening devices when there is no medical/surgical treatment that will resolve their hearing loss or if they are not candidates for medical/surgical intervention. For children, they may need an amplification system before they are old enough for specific surgical interventions that will later resolve conductive hearing loss. The encouraging news for individuals with permanent hearing loss is that there are treatments for all types and degrees of hearing loss at this time. The treatments will not restore normal hearing but should assist the individuals in their daily communication activities and provide a safe environment in which to function.

Pursuing amplification is a process that continues for the life of an individual. There is the initial process of selecting, fitting, and adjusting to the hearing aids and then the ongoing process of maintenance, replacement, and upgrade of the devices over time. Therefore, the patient establishes a relationship with the individual providing their amplification as part of a larger auditory (re)habilitation process. Otolaryngologists who may be managing the medical care of patients with hearing loss also will want to have a relationship with a professional they trust to take care of their patients' amplification and auditory (re) habilitation needs. The audiologist plays this role for the patient and otolaryngologist and is educated in the area of hearing assessment and hearing aid selection and fitting. The patient is provided with complete hearing health care when in the care of both the otolaryngologist and audiologist who are coordinating their services.

GOAL OF AMPLIFICATION

The reduction in hearing sensitivity produced by hearing loss results in activity limitations and participation restrictions as defined by the World Health Organization's International Classification of Functioning, Disability, and Health (15). Solutions to these challenges will come in the form of a comprehensive auditory (re)habilitation program that will include counseling, communication training, environmental modifications, speech and language development for children, and amplification.

Amplification is only one part of a complete auditory (re) habilitation program and should be viewed in the context of a larger program.

The basic goals of a hearing aid fitting are to provide audibility for the range of sounds encountered in daily life (range of intensity levels and frequencies), to allow the listener to hear in complex (noisy) situations commonly occurring in daily communication, and to do all this while being comfortable acoustically and physically. With the advent of a variety of consumer electronics designed to couple to the ear, a newer challenge is making sure these devices couple to the hearing aid that is coupled to the ear. While maintaining comfort, the properly fit amplification system makes the world of sound accessible to the user.

BASICS OF THE AMPLIFICATION SYSTEM

A basic amplification system is depicted in Figure 164.1. Every hearing aid functions in the manner described in Figure 164.1 including an acoustic input signal to the microphone, an analog/digital (A/D) converter, an amplification stage, a digital/analog (D/A) converter, and then the electric signal being converted to an acoustic signal as it leaves the receiver (loudspeaker) and enters the ear canal. The amplification stage is contained within the digital chip and may include differential amplification at various frequencies (channels). In addition, amplification may be differentially applied to certain levels of input (e.g., soft, moderate, loud) and to certain types of inputs (noise, speech, music) based on the algorithm driving the hearing aid signal processing. These details are described later in the chapter.

HEARING AID FITTING PROTOCOLS

This chapter is meant to introduce the physician to the many options and decisions that must be made when assisting patients in the selection of the appropriate amplification system for their hearing loss, communication needs, and lifestyle. In addition, the best practice components of hearing aid verification and outcome assessment are highlighted. Since the physician may be the entry point into hearing health care, the material in this chapter should better prepare them to discuss possible amplification solutions with their patients and help prepare them for the process they will encounter in order to become a successful hearing aid user. For detailed, evidence-based guidelines for the selection, fitting, verification, and outcome assessment of amplification systems for pediatric patients, the reader is referred to the American Academy of Audiology (AAA) Pediatric Amplification Guidelines (16). For evidence-based guidelines related to the provision of hearing aids in adults, the reader is referred to the AAA Guidelines for the Audiologic Management of Adult Hearing Impairment (17).

HEARING LOSS AND CANDIDACY

The AAA Pediatric Amplification Guidelines (16) indicate, "Amplification with hearing instruments should be considered for a child who demonstrates a significant hearing loss, including sensorineural, conductive, or mixed hearing losses of any degree." (p. 2). Children are now being fit with hearing aids by the age of 6 months due to successful early identification programs and the new guidelines that suggest children should be screened for hearing loss by 1 month, diagnosed by 3 months, and fit within 1 month of diagnosis and no later than 6 months (1–3(+1)–6 goal) (18). The AAA Guideline for the Audiologic Management of Adult Hearing Impairment (17) does not specifically outline candidacy but indicates that adult amplification recommendations will be based on the hearing evaluation and the patient's reported difficulties. If an adult is having problems hearing, then he or she is a candidate for hearing assistance. A recent study (19) found that the question "On a scale from 1 to 10, 1 being the worst and 10 being the best, how would you rate your overall hearing ability?" could sort out which individuals were ready to pursue amplification (1 to 4 rating), which individuals needed more counseling (5 to 7), and which individuals were not ready to pursue amplification (8 to 10).

EVALUATION

Physical examination of the auricle, external auditory canal, tympanic membrane, and middle ear space should be conducted. It is important to recognize conditions that warrant medical or surgical intervention or findings that would preclude tolerance of a device in or over the ear. A comprehensive audiogram that includes ear-specific pure-tone air- and bone-conduction thresholds, speech reception threshold, and word recognition testing is often the starting point of the hearing aid discussion. This level of detail will not be available for an infant, and yet our goal is to fit an infant with significant hearing loss with amplification within 1 month of diagnosis. For this purpose, ear-specific thresholds (via auditory brainstem response) in one low and one high frequency will suffice to

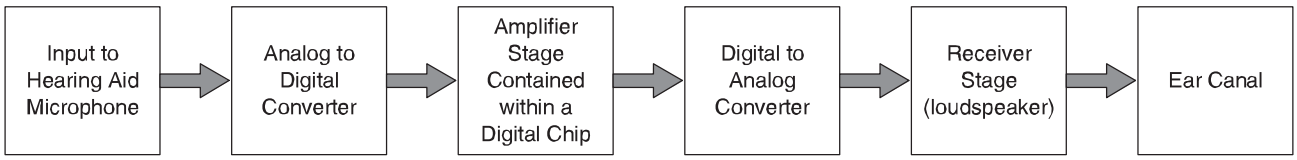

Figure 164.1 Schematic of the basic components of a hearing aid.

get the hearing aid fitting started. In the case of infants and young children, diagnostics are ongoing and the hearing aid fitting will be altered as more data related to the child's hearing loss are gathered.

With the adult patient, there are other assessments that will assist in making recommendations related to specific hearing aid configurations and technology. The quantification of frequency-specific thresholds of discomfort has been found to improve the hearing aid fitting (20). In essence, the individual's dynamic range needs to be defined in order to appropriately tune the hearing aid to produce outputs for soft, moderate, and loud sounds all within the audible but comfortable range for the individual. The lower boundary of the dynamic range is defined through threshold assessment. If thresholds of discomfort are not measured individually, then we are allowing the upper boundary of the individual's dynamic range to be defined as an average for the population. Measures of uncomfortable loudness are simple to perform and add to the precision of the hearing aid fitting. If these measures are not accomplished prior to the fitting, the clinician must be sure to verify that the individual's tolerance level has not been exceeded by use of average data through a verification procedure prior to the individual leaving the clinic.

An assessment of the individual's speech comprehension in noise also may be considered prior to recommending various amplification features. Two commonly used speech in noise tests include the Hearing in Noise Test (21) and the QuickSIN (22). A signal-to-noise ratio value is determined from these tests and can be compared to the performance of normal listeners. The QuickSIN provides ranges that relate to technology recommendations (e.g., use of directional microphones, use of assistive listening devices). In addition, the results can be very helpful in counseling the patient about realistic expectations when communicating in noise and potential environmental manipulations that may be necessary.

There is compelling evidence that if individuals want to hear in noise, they need to use two hearing aids if they have hearing loss in both ears (23). With that said, there are individuals who have binaural interference meaning that sound coming into one ear is interfering with the processing of sound from another. A dichotic test requiring hearing from both ears in order to successfully complete the test can be used to identify individuals who may be better off with one hearing aid rather than two (24). Some clinicians prefer to proceed with fitting two hearing aids allowing the individual to experience bilateral amplification and to compare that with wearing one hearing aid. This allows the hearing aid user to be part of the decision.

With these objective data in hand, the clinician will want to conduct an interview with the patient in order to assess current communication challenges, communication needs at home, in social situations, during hobbies or weekend activities, and in the workplace or school setting. In the case of a young child, the interview will be conducted with a parent or guardian. Older children should be engaged in this process. Answers to these questions may impact style, feature, and signal processing decisions as well as bring up the need for alternate solutions. For instance, if an individual is an avid bicyclist, then a style of hearing aid that can be worn comfortably with a bike helmet will be essential. In addition, the clinician may want to recommend special solutions to deal with moisture from rain and perspiration associated with this activity (see a list of special hearing aid solutions in Table 164.1). There also are systematic questionnaires available to assist in this part of the assessment including the Abbreviated Profile of Hearing Aid Benefit (25), Client Oriented Scale of Improvement (26), and the Expectations Worksheet (27). Identifying the patient's current expectations of amplification can be very helpful for creating appropriate recommendations and for motivating a conversation about realistic expectations (e.g., amplification does not return normal hearing).

PRESELECTION DECISIONS

Once the clinician is knowledgeable about the individual's hearing status, communication needs, and lifestyle, there are a variety of preselection decisions to be made. Currently, there are fewer decisions that have to be made prior to ordering the devices than in the past because many hearing aids now contain options to turn on or off various features (e.g., volume control, directionality), but some decisions continue to impact the device that will be ordered for the patient. These decisions are outlined below.

ROUTING OF THE SIGNAL

The signal from an amplification device can be delivered via air or bone conduction. In the case of a cochlear implant, the signal is electric. Cochlear implants are used by individuals with severe to profound hearing loss who do not receive benefit from traditional amplification. The needs of these patients and this technology are covered elsewhere in this text. There is evidence to encourage unilateral cochlear implant users to continue or start to use amplification on the non-implanted side (28,29). For the majority of patients with sensorineural hearing loss, an air conduction system will be recommended. Depending on the configuration of the hearing loss, various amplification arrangements may be pursued. The individual with bilateral hearing loss generally will benefit from amplification in both ears.

The individual with severe unilateral hearing loss (single-sided deafness or unaidable hearing on one side due to extremely poor clarity) may consider several recommendations that would include (a) continuing to rely on the good ear without amplification (this poses problems whenever the individual is trying to listen to someone on his/her "bad" side), (b) using a CROS (contralateral routing of signal) system where a microphone is placed on the "bad" ear and

the signal is transferred (FM transmission) to a device that delivers the sound to the good ear, (c) a bone conduction hearing aid or device on the "bad" side that picks up sound from that side and delivers it to the "good" cochlea via bone transmission, and (d) a transcranial CROS that works in the same manner as the bone conduction aid but provides such an intense air conduction signal in the "bad" ear that the sound crosses over to the "good" cochlea via bone conduction. If the individual has some hearing loss in the "good" ear as well, a bilateral CROS (BICROS) system that not only provides a transfer of the signal from the "bad" ear but also provides amplification to the "good" ear can be used.

In the case of the bone conduction solution, this can be achieved through a bone vibrator coupled to the head on a tight band or through a bone vibrator attached to the skull with a titanium screw. There are two devices on the market currently used for this surgical solution. Both function in a similar manner. An implanted bone conduction hearing device is a type of hearing aid that transmits sound to the inner ear via bone conduction. It is appropriate to use in cases of conductive hearing loss, mixed hearing loss, or single-sided deafness. It also may be used for patients with hearing loss who cannot wear an air conduction hearing aid due to malformations or pathologies of the outer and/or middle ear. After the patient has been identified as a candidate based on the audiologic and medical examinations, a titanium screw is surgically implanted into the mastoid region of the temporal bone. The external portion of the screw, typically referred to as the abutment, is used to anchor the bone conduction unit to the head. The titanium fixture must become osseointegrated before the bone conduction unit can be affixed. The processor converts incoming sound to vibrations that stimulate the cochlea. Another option more recently available provides an abutment free option by using an implanted magnet to affix the external sound processor to the titanium implant. This is covered in greater detail in Chapter 163.

Another device based on bone conduction transmission is attached to maxillary teeth through a dental appliance that is removable. Sound is picked up by a microphone processor, and the signal is wirelessly delivered to the oral appliance. This device also is indicated for conductive or mixed hearing loss and single-sided deafness.

The individual with conductive hearing loss who does not wish to or cannot have medical/surgical intervention may pursue amplification. An air conduction hearing aid

can be used for mild-to-moderate conductive losses that are not accompanied by malformation of the outer ear or drainage. For conductive losses that are accompanied by malformations of the pinna and ear canal or that produce ongoing drainage, a bone conduction amplifier will be a better choice. In the case of pediatric patients, they may have a time period when they are waiting for their system to mature enough for surgical intervention (reconstruction) and will need to use a bone conduction hearing aid in order to keep the cochlea stimulated during this waiting period. As described above for solutions to single-sided deafness, a bone vibrator on a tight headband or an implanted bone vibrator can be used for this purpose. Currently, the FDA does not allow implantable bone vibrators for children under 5 years of age.

STYLE

For patients receiving air conduction amplification, the discussion of the style of the hearing aid will be driven by the patient's hearing loss, communication needs, lifestyle, and personal preferences. The discussion will start with defining whether the individual is interested in an extended wear option or a traditional wear option. Currently, there is one extended wear product commercially available, the Lyric hearing aid (Fig. 164.2). This hearing aid is a single-channel, analog device that is disposable. Because of this level of technology, the battery life for this hearing aid is drastically increased. The Lyric is placed deep within the ear canal by the clinician after setting the programming based on coupler measurements (a probe microphone cannot fit in the ear canal when the device is inserted). The user has a magnet that allows them some control over the volume of the device. The Lyric provides 24/7 hearing with the user being able to shower and carry on most daily activities with the device in place. When the device stops working (this could range from a few weeks to 3 months depending on moisture, cerumen, etc.), the user has a tool that allows removal. The patient subsequently returns to the clinic or office for placement of a new device. To be a successful extended wear user, the individual needs to have reasonably cylindrical, straight ear canals. The manufacturer provides a systematic way to determine candidacy, sizing, and placement. The pricing structure of this device currently is quite different from traditional wear hearing aids and includes paying a yearly subscription fee.

Recently, several manufacturers have introduced a deep insertion traditional wear hearing aid. This provides the benefit of the sound source being right near the tympanic membrane, which provides a wider, audible high-frequency bandwidth. However, this hearing aid is removed each night and batteries are replaced when they stop functioning (as opposed to the hearing aid being disposable). A picture of the new "invisible in canal (IIC)" hearing aid is provided in Figure 164.3.

Individuals interested in traditional wear hearing aids have several styles and coupling options (connecting the hearing aid to the ear) to consider. Figure 164.4 provides pictures of the various styles of hearing aids currently available along with a list of pros and cons. Figure 164.5 provides the same type of information but focused on the pediatric patient whose outer ear will be growing over the first years of life. For pediatric patients, the behind-the-ear style is recommended because this style reduces the cost of refitting (only the earmold that couples the hearing aid to the ear needs to be replaced when the outer ear grows), provides the greatest amount of flexibility in terms of power (in case the hearing changes), offers a variety of features (ability to connect to assistive listening devices, etc.), and requires the least amount of maintenance. The final decision on style will be a balance of the clinician's recommendation and the patient's preferences.

Some of the most important changes in style recently have included the extended wear option, deep insertion

completely in the canal (CIC), and ability to provide more gain in a CIC with advances in feedback management, which has allowed more users to pursue this style without operating at the limits of amplification. In addition, the behind-the-ear (BTE) hearing aid has become a popular option with adults due to miniaturization (see a mini BTE in Fig. 164.4) and the use of slim tube rather than standard tubing to couple the aid to the ear canal. In addition, with the advent of improved feedback management systems, open fit BTEs (Fig. 164.6, panel B) that leave the ear canal much more open than traditional earmolds (Fig. 164.6, panel A) have improved comfort and fit for many individuals. There has been some confusion in terminology with clinicians referring to any BTE with a slim tube as an "open fitting." The slim tube can be connected to a dome allowing for an open fit, but it also can be connected to a standard earmold producing a closed fit for individuals who have more significant hearing loss. Figure 164.7 provides the various coupling arrangements that currently are available for BTE fittings. With the goal of slimming down the BTE but maintaining a reasonable battery life (1 to 2 weeks), manufacturers have introduced the receiver in the canal (RIC) BTE. The RIC is compared to a receiver in the aid (RITA) in Figure 164.8 (RIC on the left and RITA on the right). An electrical connection from the BTE to the receiver housed inside the dome (or earmold) can be seen. By moving the receiver into the ear canal, the BTE case can be smaller while also holding a larger battery. The consequence, however, is cerumen damage to the RIC, whereas when the receiver is cased in the BTE, it is removed from potential cerumen damage. Because of this and the desire to make the CICs have a deeper insertion yet remain more dependable, cerumen guards (Fig. 164.9) are a standard on all hearing aids with receivers in the canal.

EARMOLDS

For any of the BTE styles, the hearing aid must be coupled to the ear. The clinician will make a variety of decisions related to coupling in terms of tubing size, open or closed fitting, venting within traditional earmolds, and earmold material (soft, hard, combination). These decisions will be based on the degree and configuration of hearing loss, the consistency of the individual's pinna and ear canal, and the style of hearing aid the individual would like to pursue. Venting provides an air path through the earmold to the ear canal. Venting can provide ear canal aeration and comfort with the flow of air in and out of the ear. In addition, the occlusion effect (the perception that one's own voice is loud and boomy) will be reduced with a large vent. The occlusion effect also can be reduced with a long canal portion of the earmold that reaches close to the bony portion of the ear canal. Vents are acoustic filters and will pass low frequencies both into the ear and out of the ear. Individuals with normal hearing in the low frequencies will be able to hear these frequencies naturally if a vent is provided.

For the pediatric patient, it will be most common to use a soft material that tends to reduce feedback and provides a comfortable fit. Earmolds will need to be remade every 2 months for an infant and then about every 4 months for a toddler. The young child will continue to need new earmolds every 4 to 6 months. Once the earmold is not fitting well, there is a greater chance of feedback. Feedback (whistling) is caused when amplified sound can leak out of the ear canal and reach the microphone to be re-amplified. One way to reduce this is to turn the volume down on the hearing aid. This, of course, is counter to the goal of amplification. In addition, most pediatric fittings do not activate the volume control because the clinician does not

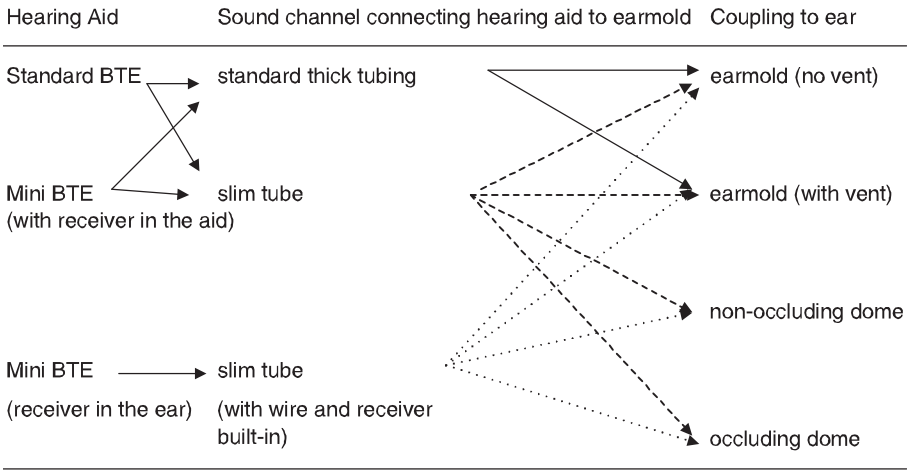

Figure 164.7 Chart of combinations of BTEs, tubing, and coupling to the ear.

want the child turning down (or off) the hearing aid. With the advent of improved feedback management strategies, some feedback will be reduced, but a poor fitting earmold cannot be compensated for by feedback management. The child should be seen proactively to replace earmolds prior to feedback problems.

TELEPHONE ACCESS

Individuals across the life span need access to telephone communication. No one should be provided with an amplification system that does not include a telephone solution. The clinician is now faced with creating solutions for landline phones, cell phones, and hands-free options. The challenge with telephones is that even with an excellent fitting earmold and the use of advanced feedback management, when a hearing aid user holds a telephone (or anything else) close to a hearing aid microphone, the hearing aid will most likely produce feedback. Landline phones emit an electromagnetic signal that can be picked up by a hearing aid telecoil circuit. When the hearing aid (BTE or ITE) is switched to the telecoil circuit, the microphone is turned off, thereby eliminating the chance for feedback. Some hearing aids include automatic telecoils that are triggered by the magnet in the telephone when the telephone comes into proximity of the hearing aid. There is quite a bit of variability among telephones in terms of strength of electromagnetic leak and magnet. The key to successful use with a telecoil is instructing the BTE hearing aid user to hold the telephone above their ear near their hearing aid. This is strange for the individual in the beginning because they are used to holding the phone to their ear canal. The hearing aid user may need to try several phones before they find one that works well with their hearing aid. Individuals with open fit BTEs who by definition will have good low-frequency hearing may find that they can continue to use the phone successfully by holding it to their open ear canal. If this is not sufficient, they may need to simply raise the volume on the telephone slightly. Most patients including many children now use cell phones. Normally hearing individuals use cell phones by holding them to their ears or through a Bluetooth wireless connection. Depending on the style of the hearing aid, the hearing aid user also will have these options in slightly modified forms. A chart of

[a]By law, some cell phones do have an induction signal. If this is the case, then the users can use their telecoil.

possible solutions for each style of hearing aid is provided in Table 164.2.

ABILITY TO COUPLE TO OTHER SOUND SOURCES

Individuals who are pursuing hearing aids may already couple other listening devices to their ears. These might include Bluetooth phone receivers (discussed above), MP3 earphones, dictation earphones, stethoscopes, and in-ear monitors (anesthesiologists, newscasters, etc.). The variety of possible solutions are too varied to discuss in the context of this chapter, but the individual responsible for selecting the hearing aid style, earmold coupling, and technology will want to know about these devices in order to include them in the final hearing aid selection decision.

ABILITY TO COUPLE TO ASSISTIVE LISTENING DEVICES

Assistive listening devices are designed to overcome problems of noise and distance for the hearing aid user (23). The basic assistive device provides an offsite microphone (separate from the hearing aid) that is placed as close to the sound source of the signal of interest as possible. The transmitter attached to the microphone then sends this signal via a transmission technology (FM, infrared, electromagnetic) to be picked up by a receiver that will then direct the sound to the hearing aid or directly by the hearing aid with a built in receiver. Figure 164.10 provides the various iterations that are possible with current assistive listening systems. For the adult population, assistive listening devices are often pursued if they have specific listening situations that are identified during the hearing aid selection process that cannot be solved by hearing aids or after the selection process if the individual finds they are still not communicating as well as they would like in challenging situations. The goal of the clinician is to predict the need for assistive technology, so the selected hearing aids will be compatible with receiving the transmission signal. There also are intermediary devices available that receive the signal and pass it on to the hearing aids. Not all brands or styles of hearing aids are able to couple with assistive listening devices. With the advent of Bluetooth technology, many hearing aid users would like their hearing aid to pick up a Bluetooth signal. This certainly would create a variety of universal solutions for phone, computer, and television listening. Unfortunately, at the current time Bluetooth transmission and reception creates a great deal of battery drain that cannot be supported in current hearing aids. Therefore, a Bluetooth signal must be received by an intermediary device (usually worn around the neck), and then an induction signal is passed on and received by the hearing aids.

REMOTE CONTROL

Some patients would like to have quite a bit of control over the hearing aids, and some patients want to put the hearing aids in and forget about them. This is an issue that is best defined during the preselection process. Some of the styles of hearing aids (BTE, ITE) will come with controls that are accessible on the case (i.e., program button, volume control) if the clinician orders them. Smaller hearing aids (e.g., CIC) will have very little room for controls. In these

[a]Microphone near sound source or device directly plugged into sound source (e.g., television sound jack, MP3 sound jack).

Figure 164.10 Chart of assistive listening device transmissions and coupling choices.

cases, the individual may like to have a remote control. The remote control may control volume and program selection. At least one manufacturer now has an "app" for volume and program control that can be accessed through a cell phone.

BATTERIES

All hearing aids continue to need batteries in order to operate. Hearing aid battery sizes include 675, 13, 312, and 10 batteries with 10 being the smallest (generally for CICs and mini BTEs). Patients will experience a range of battery life from 3 to 5 days up to 2 weeks depending on the style of hearing aid, size of battery, and number of hours the hearing aids are used.

HEARING AID FITTING

Achieving Audibility

The challenge of fitting amplification is fitting the range of sound one encounters in day-to-day life into the reduced dynamic range of the individual with hearing loss. Figure 164.11 shows an audiogram of an individual with moderate to profound sensorineural hearing loss. The X's and O's indicate the pure-tone threshold levels at which the individual can hear sound 50% of the time. Therefore, the individual cannot hear sound below that level. In this example, we will say that the individual will become uncomfortable when sound is presented at around 105-dB HL. So, at 1,000 Hz, an individual with normal hearing would have a dynamic range of 105 dB (0- to 105-dB HL). The individual whose hearing loss is shown in Figure 164.11 has a dynamic range of 40 dB in the right ear at 1,000 Hz (threshold of 65 and discomfort level of 105). In order to return audibility for soft, moderate, and loud sounds while maintaining comfort, the hearing aid employs expansion and compression signal processing. Compression allows gain to be differentially applied according to input level with more gain applied to soft sounds and less gain applied to loud sounds (30). For soft input levels, enough gain to achieve audibility (to produce an output greater than threshold) is applied; there will be less gain applied to a moderate sound and even less to the louder sounds. This allows for audibility across the wide range of input levels to be compressed into a much smaller range of output levels. Expansion is used to reduce circuit noise (microphone noise) and to make very low-level sounds less annoying. In essence, it is the opposite of compression and applies very little gain to extremely quiet inputs (inputs below the compression threshold) and then increases gain as the soft inputs increase. Compression and expansion signal processing are described by the threshold at which they activate (input level), the ratio of compression or expansion (e.g., a typical compression ratio for hearing aids set for a mild-to-moderate sensorineural hearing loss will be 2:1 to 3:1), and attack and release time. There is consensus regarding

the need for fast attack times. The research has been less clear related to release times. The most recent study (31) indicated that there is little difference between slow and fast release times, and both may have uses for different signals. At this point, attack and release times are set by the manufacturer and are not controlled by the hearing aid fitter. Compression threshold can be manipulated in the hearing aid fitting, and compression ratio is altered whenever gain is increased differentially for soft versus loud sounds.

As can be seen in Figure 164.11, many hearing losses change across frequencies with more hearing loss in some frequency regions as opposed to other frequency regions. In order to account for these changes and the resulting need to differentially program the hearing aid gain to produce audible signals across input levels, channels are used in hearing aids. A channel is a filtered frequency area that has its own amplifier and therefore can have specific compression characteristics (threshold and ratio). In Figure 164.11, the low-frequency channel would have different compression characteristics than the mid- or high-frequency channel. In order to obtain optimum speech intelligibility, 2 to 4 channels are necessary (30). Many current hearing aids have 10 to 20 channels available. The larger number of channels is related to their use in feedback management, which is discussed later in the chapter.

The bandwidth of a hearing aid, which is operationally defined by the lowest and highest frequency where audible output for the hearing aid user can be achieved, also contributes to audibility. Most commercially available hearing aids have output up to 4,000 to 5,000 Hz. The limits of the high-frequency bandwidth are dictated by the digital sampling used by the hearing aids. If the hearing aid is sampling at a rate of 10,000 Hz, then the bandwidth will be 5,000 Hz (half the sampling rate). Higher sampling rates would result in a wider bandwidth but also result in increased battery drain that would be unacceptable to the user. For children learning speech and language, a 5,000-Hz bandwidth is not adequate (32). A bandwidth out to 8,000 to 9,000 Hz is necessary for the correct perception of the sound /s/ for young children (33–35). Adults who can rely on context are able to fill in missing sounds and information from the amplified signal, but this requires more effort than if the signal was completely audible. The major manufacturers are all working on increasing the bandwidth of their hearing aids including the low-frequency limits that contribute to enjoyment of music.

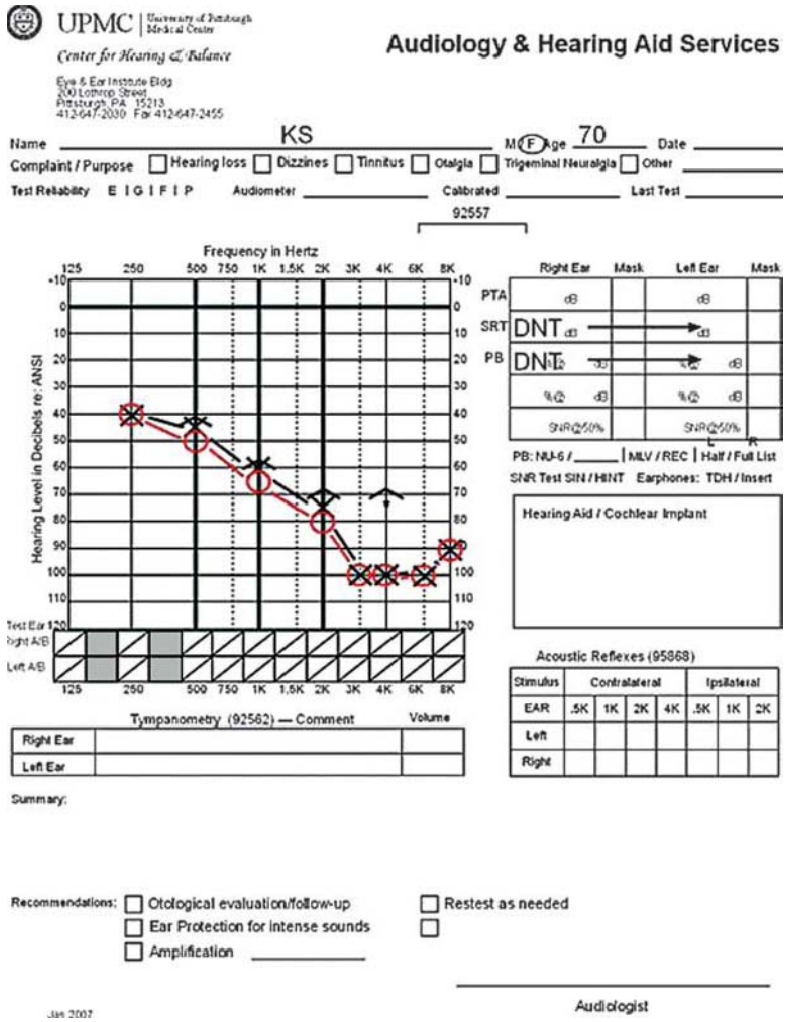

Figure 164.11 Example audiogram.

Recently, frequency lowering has been reintroduced into the hearing aid market in order to resolve audibility issues for individuals who cannot access high-frequency audibility because of the severity of their high-frequency hearing loss (severe to profound degree of loss in the high frequencies with mild-to-moderate hearing loss in the low to mid frequencies). Frequency lowering comes in three forms currently: nonlinear frequency compression, linear frequency transposition, and spectral feature identification. In nonlinear frequency compression, a cut off frequency is chosen based on the hearing loss, and the frequencies above that point are compressed into an audible range for the listener. In linear frequency transposition, the frequencies above the cut off are literally shifted down on top of other frequencies. In spectral feature identification, identifies high-frequency features in the signal and replicates those features at a lower frequency. In each case, the signal is a distortion of the original but also provides audibility to sounds that would not be audible. Success in using this signal processing has been reported with children, but the utility with adults who have not heard this type of sound previously is less clear (36–38). In either case, auditory training would be a reasonable recommendation as individuals learn to use these new sounds.

The hearing aid/cochlear implant hybrid currently under investigation also is aimed at the type of hearing loss that has no more than moderate severity in the low frequencies with profound hearing loss in the high frequencies. Once again, the new signal that combines electric and acoustic hearing will most likely require some level of auditory training to become accustomed to the signal.

Feedback management strategies also can be grouped under technologies that potentially increase audibility. The general goal of a feedback management system is to provide more usable gain prior to feedback. Manufacturers employ different strategies for feedback management, and the success of these strategies varies. Commonly, the hearing aid identifies feedback through the ongoing analysis of the incoming signal by identifying a pure-tone signal that is not commonly heard in day-to-day communication. Once this signal is identified, the gain in the specific channel that corresponds to the frequency can be temporarily reduced. Some strategies provide a matching signal that is 180 degrees out of phase in order to cancel the sound (39). Feedback management is a problem if the individual actually is trying to listen to pure tones (e.g., in some musical compositions or if the individual is a musician), and therefore many hearing aids come with a "music" program that disables the feedback and noise reduction features so music will remain intact.

HEARING IN NOISE

The majority of commercially available hearing aids are connected to a computer for programming. This includes adjusting the gain for different frequency channels as a function of input level, selecting feedback management, and frequency shifting as described above. In addition, most levels of technology come with features meant to impact the listeners experience in noise since hearing in noise is one of the most common challenges for individuals with hearing loss. The first recommendation that should be made to the hearing aid user is to wear the amplification full-time and to wear two hearing aids (23). Both of these solutions will assist the hearing aid user in hearing in noise. Individuals who try to use amplification part time often complain that sounds seem too loud and that all they hear is noise and not the signal of interest. In these cases, the brain continues to try to adjust to the new amplification without receiving a consistent, full-time signal.

The majority of hearing aids use digital signal processing. It is this processing that has allowed for more and more complex algorithms that evaluate and process the incoming signal. The clinician responsible for verifying the hearing aid fitting also will be the person setting these various parameters.

DIRECTIONAL MICROPHONES

One of the most important technology developments for tackling the problem of hearing in noise was the use of directional microphones on hearing aids (40,41). This technology continues to develop, and currently most hearing aids have a "smart" program that changes the microphone setting depending on the sound that is being sampled by the hearing aid. Because of the digital nature of the signal processing system, sound coming into the microphone can be sampled in real time. The signal processing algorithm analyzes the amplitude envelope of the incoming signal. If it determines that the amplitude envelope is steady state (little variation), it classifies the signal as primarily noise. If it identifies the amplitude envelope as varying, it identifies the signal as speech. When speech is the primary signal, the omnidirectional setting will be engaged. When noise is the primary signal, the directional microphone will be engaged. Within the directional microphone setting, various polar patterns of directionality can be implemented. Figure 164.12 provides a sample of polar plots that might be associated with a hearing aid. These polar plots will not look as organized when the hearing aid is actually in a person's ear since head and body baffle effects are present. In essence, a directional microphone is less sensitive to certain areas around the listener. In Figure 164.12, panel C, a cardioid polar plot is depicted. The individual will have less sensitivity to sound in the back and more sensitivity in the front. Successful use of directional microphones continues to demand environmental manipulation from the patient. The patient must position themselves so the signal of interest is in front and so the majority of unwanted noise is in back. Further, if the individual is trying to communicate in a highly reverberant room, the directional microphones will be of little assistance because noise will

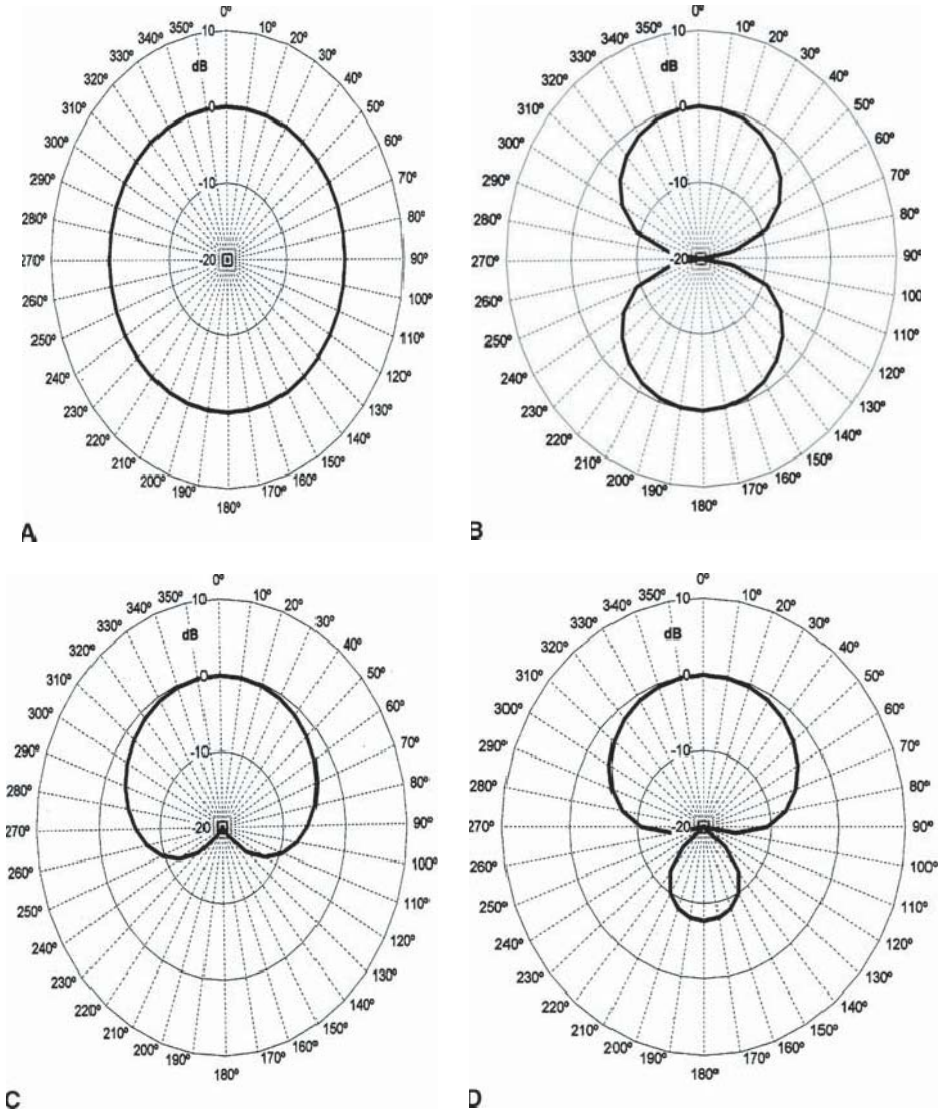

Figure 164.12 Polar patterns for **(A)** omnidirectional, **(B)** bidirectional, **(C)** cardioid, and **(D)** hypercardioid microphones.

be surrounding the individual as it bounces off hard surfaces. This is why investigators have found that directional microphones are considered useful in about 25% of communication situations for adults (42). The hearing aid user has to understand that the hearing aids do not know the intent of the listeners (i.e., what sound source the listener is trying to listen to) so the listeners must orient themselves to that signal.

Traditionally, directional microphones were not recommended for young children based on the philosophy that we do not want to reduce the input to the hearing aid since quite a bit of childhood learning comes through incidental listening. Two laboratories (43,44) have focused on the use of directional microphones in young children recently coming to opposite conclusions. The Australian Laboratory (44) currently recommends using directional microphones (and noise reduction signal processing) in all hearing aids regardless of age, and the US Laboratory (43) currently does not recommend the use of directional microphones with children until they are old enough to understand and manipulate the settings (~12 years old).

DIGITAL NOISE REDUCTION

Digital noise reduction functions in the same manner as directional microphones in terms of when it is activated. If the hearing aid identifies the incoming signal as steady state, it assumes that the primary signal is noise and that the signal should be reduced. Digital noise reduction may be employed as a function of frequency channels, thereby reducing gain in some frequency regions more or less than others. The reality of the signal processing is that gain is reduced and therefore the noise and any speech are decreased in intensity. Therefore, it is not surprising that studies have not shown an increase in intelligibility when digital noise reduction is employed (45). Investigations

have shown an increase in comfort and a decrease in listening effort with the use of digital noise reduction (45–48).

OTHER SETTINGS THAT CUSTOMIZE THE HEARING AID FITTING

Current technology offers a myriad of features that may be selected or deselected depending on the fitter's and patient's preference. The clinician will want to be aware of the various default settings of manufacturers, so they do not inadvertently send the new user out with signal processing or features that they did not intend to use. Many of the more advanced technology now have the option for the two hearing aids to communicate. This can be a convenience in that the hearing aid user can adjust one volume control and both hearing aids will receive the change in setting. A more sophisticated use of this same technology is to ensure that if one hearing aid switches into the directional setting, the other hearing aid will do the same. For a previous user who is not use to this, it is worth taking a few minutes to explain what is happening.

Hearing aids now are equipped with data logging that allows the clinician to see how the hearing aids have been used. Tracking data are available to determine the number of hours per day of use, whether the hearing aids are worn in situations classified as quiet or noisy by the hearing aid, and number of times the volume was manipulated or listening programs where changed. The clinician may want to describe this feature to new users, so they are not surprised when the clinician can comment on how many hours per day they have been using the devices. The newest iteration of data logging is data learning or training. When this feature is activated, the hearing aid actually changes gain and compression settings based on the user's manipulation of the volume control over time. Studies have shown that the changes the user makes will be dependent on the original settings of the hearing aid (49,50), which simply lends support to carefully setting the instruments for audibility on the day of the fitting. There is some disagreement as to whether this feature should be turned on at the time of fitting or whether new users should have an adjustment period before this "fine-tuning" feature is activated.

Hearing aids come with a variety of alerting signals to allow the user to know when a program has been changed, when the volume has been changed, and when the battery is about to die. These signals can be in the form of beeps, or they can be set so a voice indicates the change (e.g., "battery low"). It may be a surprise to the hearing aid user to hear a voice in their ear, so it is best to test these signals while the patient is in the clinic so they will know what to expect.

PRESETTING AND VERIFICATION

The output and gain of hearing aids can be measured in a coupler or in the ear of the individual. The coupler provides a standard from which various aspects of the hearing aid response can be described. Figure 164.13 provides a picture of a BTE hearing aid attached to a coupler. When the test box is closed it creates a small anechoic chamber. A sound source is played from the speakers, the hearing aid microphone picks up the sound, and the output or gain of the hearing aid attached to the coupler is measured by a microphone attached to the other side of the coupler. The coupler mimics the ear canal of an average male. Figure 164.14 provides an illustration of output for a moderate input signal and maximum output measured in a coupler. A record of the hearing aid gain after the hearing aid has been programmed for the individual may be kept, so if there are any problems with the hearing aid, the response can be checked quickly and accurately. Coupler measures also can produce information about distortion in the hearing aid, circuit noise, and battery drain. For the purpose of verifying a hearing aid fitting and programming the output across frequencies and intensity levels, real ear probe microphone measures are used. In all cases of verification, the goal is to measure the output of the hearing aid that will be achieved at the individual's tympanic membrane and to compare it to evidence-based targets of the desired output.

Figure 164.13 Behind-the-ear hearing aid connected to a coupler and ready to be evaluated in a test box.

Both the Pediatric Amplification Guidelines (16) and the Adult Amplification Guidelines (17) provide recommendations for verifying that soft, moderate, and loud signals are audible. The verification technique consists of placing a microphone in the ear canal with the hearing aid inserted. Soft, moderate, and loud speech or speech-like signals are played through a loudspeaker, and the resulting output in the ear canal is measured and displayed against the individual's frequency-specific thresholds displayed in sound pressure level (SPL). For this to be an accurate assessment of audibility, the individual's hearing thresholds have to be converted from hearing level (HL) to SPL. The real-ear-to-coupler difference (RECD) measurement is used to convert HL to SPL data (51,52).

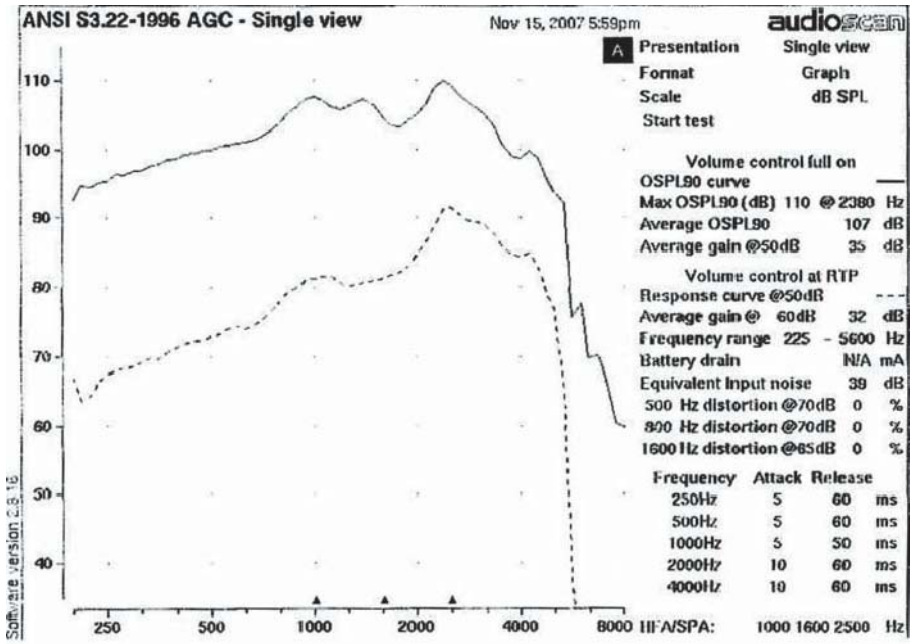

Figure 164.14 Example coupler response. The *x*-axis displays frequency (250 to 8,000 Hz) and the *y*-axis displays output (dB SPL). The *solid line* is the output for a loud signal (maximum output) and the *dashed line* is the output for a 50-dB SPL. A variety of other standard hearing aid measures are displayed on the right side of the graph.

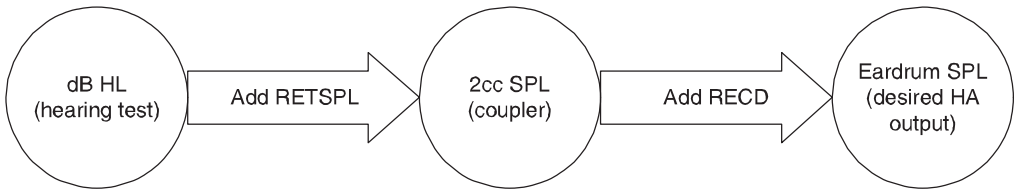
Figure 164.15 provides the calculation used when applying RECD to HL thresholds in order to obtain SPL thresholds. Figure 164.16 provides the threshold data in SPL from the patient whose audiogram can be seen in Figure 164.11. RECD has been applied to the original HL thresholds and the resulting SPL thresholds are plotted, so the hearing aid output can be compared to the individual's dynamic range. This correction in the conversion from HL to SPL is especially critical when fitting children due to the difference in size between adult and pediatric ear canals. The average conversion data are based on average adult data. The resulting SPL thresholds are used to provide target output levels for the soft, moderate, and loud inputs across frequencies measured in the ear canal of an individual. Both the DSL (i/o) v.5 and the NAL/NL1 v.2 are evidence-based fitting formulae that will produce targets for this purpose (53–55). In the case of an infant or young child, the clinician armed with the RECD data can preset the hearing aid using coupler measurements and be able to evaluate the SPLs that will be achieved at the tympanic membrane of the individual child. The lines in Figure 164.16 show the output of a hearing aid for a child where thresholds and RECD were used to preset the hearing aid. The hearing aid was manipulated until the output for the soft, moderate, and loud levels closely matched the DSL (i/o) v.5 targets.

During a hearing aid fitting, the hearing aid is first programmed by entering HL threshold data into the manufacturer's software. The software then makes a calculation of gain and other parameter settings (compression threshold, etc.) to provide a starting place for the fitting. Data indicate that this starting point can vary drastically between manufacturers (56–58) and will not guarantee audibility (in most cases high-frequency signals will not be audible). Therefore, measurement and tuning of the hearing aid to achieve audibility is essential, and the "first fit" from the manufacturer can only be considered a starting place.

Any features that have been selected for the hearing aid users should be verified as well. This would include directional microphones and telecoils. The directional microphone can be assessed using a front-to-back ratio, which is completed by setting the hearing aid to the directional setting and completing probe microphone measures as



RETSPL: Reference Equivalent Threshold Sound Pressure Level
RECD: Real Ear to Coupler Difference

Figure 164.15 Converting HL to SPL thresholds using real-ear-to-coupler difference (RECD).

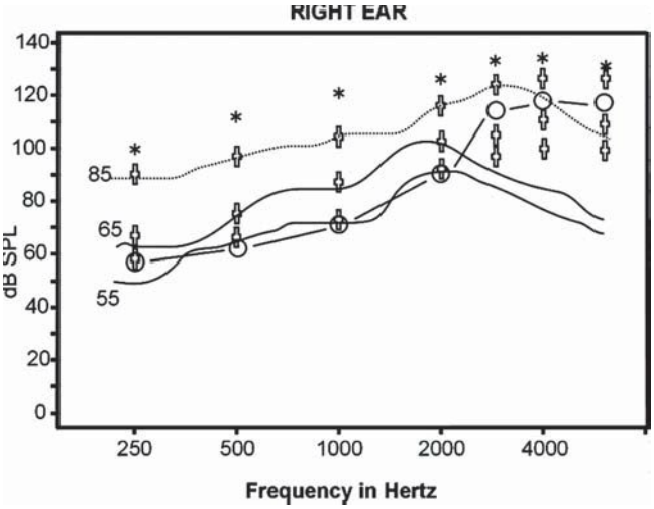


Figure 164.16 Real ear probe microphone output measures. This standard measure of hearing aid verification shows the output of the hearing aid for three input levels (55-, 65-, and 85-dB SPL). The plus signs illustrate the target output for each level across frequencies. Frequency is displayed across the *x*-axis, and output (dB SPL) is displayed on the *y*-axis. The Os represent the right hearing thresholds and the * represent the output that would be uncomfortable for this person. The range between these two symbols is the dynamic range.

described above. Then a second probe microphone measure is made with the speaker behind the individual. The output measurement behind the individual (with the directional microphone activated) should be less than the output measured with the speaker in front of the individual since the directional microphone should be less sensitive to sound coming from behind.

It is advisable to practice using the telephone with the new hearing aids prior to the patient leaving the clinic. The clinician may want to have the individual call a recording of the weather in order to have a signal to listen to through a landline and cell phone.

A recent study (59) found that there was a significant relationship between the testing conducted at the fitting and the patient's perceived benefit from and satisfaction with amplification. Measurement of loudness discomfort, use of real ear probe microphone measures, and some form of outcome assessment added to the individual's perceived satisfaction.

ORIENTATION

Once the hearing aid is programmed and the various settings have been selected, the new hearing aid user or parents of young children with hearing aids need to be oriented to the use and care of the amplification devices. Table 164.3 includes the various items that should be explained and practiced prior to the adult or child leaving with the hearing aids. As soon as a child is old enough to care for the hearing aids, he/she should be encouraged to do so. All of the care givers involved in a child's care need to understand the care and use of the hearing aids.

OUTCOME ASSESSMENT

Whereas verification measures that the hearing aid is producing audible signals, outcomes assessment evaluates whether the goals of the hearing aid fitting have been achieved. These goals may be related to speech and language development for a child or communicating effectively in particular situations for an adult (e.g., work, home). Several psychometrically sound instruments are available for use in outcome assessment with the adult and include the Independent Outcome Inventory for Hearing Aids (60) and the Satisfaction with Amplification in Daily Life (61). Objective tests of speech recognition are not widely recommended for outcome assessment because the testing environment in the clinic is controlled and artificial compared to the communication situations in which hearing aid users will find themselves. There are a variety of surveys currently used to assess amplification outcomes in children (62–71) that focus on various individuals in the child's communication environment including parents and teachers.

ASSISTIVE TECHNOLOGY BEYOND THE HEARING AID

Some hearing aid users may find that they require further assistance when communicating in noise or at a distance. If environmental manipulations will not solve these challenges, then the clinician may want to recommend assistive listening technology. Figure 164.11 provides examples of the types of transmission signals and coupling arrangements that can be used with assistive listening devices. Assistive listening

devices consist of a microphone or direct line into a sound source. The sound is then transmitted via a wireless technology (FM, infrared, induction) that is picked up by a receiver either worn on the body of the hearing aid user or housed within the hearing aid. If the signal has been picked up by a body-worn receiver, then there is one more transfer to the hearing aid via direct audio input (hardwired) or induction. Listeners who do not use hearing aids can use earphones to receive the signal from an assistive listening device.

Adults will find these systems useful in meeting situations and restaurants where either background noise or distance is preventing them from functioning well in these challenging environments. Children will benefit from assistive listening systems in a variety of situations. For the very young child, an FM system may be used so the child can hear mom, dad, or the radio/CD while sitting in the backseat of a car. Assistive listening devices will be used in classroom situations to ensure that the child with hearing loss can hear the teacher. For children with personal hearing aids, an FM system will most often be recommended. For a child with minimal hearing loss or unilateral hearing loss, a sound field system may be recommended. Soundfield equalization systems consist of a microphone and transmitter worn by the teacher that send sounds via FM transmission to speakers placed throughout the room or to a single speaker placed on the student's desk. These systems equalize the level of sound throughout the room and create a sound environment that puts every child in the front row (with the best possible signal level and signal-to-noise ratio). Data have revealed that these systems are helpful to all of the children in the classroom. The personal system (with the speaker on the child's desk) helps only the child who is sitting at that desk, but is then portable so the child can carry the lunch box–sized device to the next classroom.

The coupling stage of these systems require that the hearing aid be compatible with the assistive listening device. Even if an assistive listening device is not ordered at the time of the hearing aid fitting, it is wise to discuss these options so the selection of the hearing aid has the potential for compatibility with assistive devices that may be pursued in the future. Currently, behind-the-ear hearing aids can have built-in FM receivers that are very attractive to users because there are no other cords and boxes to be worn.

As part of the communication assessment conducted with the adult or parents of children with hearing loss, the clinician will want to discuss the patient's ability to alert to warning signals. For the child, the clinician may want to refer to the Developmental Index of Auditory Listening (66) to get a sense of when to expect children to alert to and use various auditory signals (e.g., alarm clocks, phone use). This instrument will help guide the clinician and family in terms of what technology may allow the child to continually seek independence in using auditory signals. Important alerting signals are listed in Table 164.4. Individuals with hearing loss will need to alert to these signals when they are not wearing their hearing aids since traditional wear hearing aids are not worn during sleep. There are a variety of signals that can be used to make the person aware of an alerting signal including louder sounds, lower-frequency sounds, vibrations, lights, and fans. Choosing the best signal for the individual will be a process. Some individuals may want the alerting signals coordinated so they can wear a wristband and have a differential tactile signal depending on what signal is being triggered (i.e., baby monitor, doorbell, phone ringer, etc.).

SUMMARY

Providing complete hearing health care requires services of audiology and otolaryngology. The use of hearing aids and assistive listening devices is part of a larger auditory (re) habilitation plan that should be individually designed for the patient. The goal of amplification is to return audibility for soft, moderate, and loud sounds while maintaining comfort. There are a variety of hearing aid features and signal processing that allow the clinician to further tailor the solution to the individual. The clinician involved in the provision of amplification is challenged with monitoring developments in hearing aid technology that are introduced every 3 to 6 months. The clinician is required to be a critical consumer not only of published data (which can be three cycles behind the technology currently on the market) but also of marketing materials supplied by manufacturers. The clinician is the bridge between the evidence base and the consumer whose goal is to obtain a cost-effective solution to communication challenges. The clinician must understand the individual's hearing loss, communication needs, and listening environments in order to recommend a solution that will address the patient's needs while fitting into the individual's lifestyle. Properly fit amplification can significantly enhance the quality of life for the individual with hearing loss and the family (72–75).

ACKNOWLEDGMENTS

We would like to thank Lindsey Jorgensen and Leslie Cody for their assistance with specific content in the chapter. We would like to thank Randall Kesterson and Jenifer Fruit for their assistance with several of the figures.

HIGHLIGHTS

- There is some type of treatment for all degrees and types of hearing loss.
- The primary purpose of amplification is to return audibility for quiet, moderate, and loud sounds while maintaining comfort; therefore, verification techniques should be aimed at confirming these results.
- The "first fit" program used by manufacturers is a starting place but will not guarantee a properly fit hearing aid. The output of the hearing aid at the tympanic membrane has to be measured to properly program a hearing aid.
- Successful hearing aid use requires full-time hearing aid use.
- There is no one best hearing aid for everyone, but there is a best hearing aid for a particular individual, and this will be based on assessments that include communication needs and lifestyle assessment.
- An evidence-based approach should be used in recommending technology in order to avoid "overselling" technology that will not likely benefit the patient.
- Hearing well in noise requires the patient to use two hearing aids if appropriate for the hearing loss and to wear the hearing aids full-time. Other technologies that may help in noise include directional microphones and assistive listening devices.

INTRODUCTION

Magnitude of the Problem in Population

The diagnosis and management of the patient with dizziness and imbalance can be perplexing and challenging. Dizziness is a common symptom affecting 20% to 30% of the general population in the United States (1,2). Among patients 75 years of age and older, balance disorders are the most common reason for visiting a physician (3). In the elderly, falls caused by dizziness and poor balance are associated with morbidity and even mortality. Such falls constitute a major health care burden in our aging population (4). Early detection and intervention in these cases can result in significant improvement in the quality of life as well as in a decrease in disability and reduction in health care costs (4). It is, therefore, incumbent on those who diagnose and treat dizziness to recognize the complexity of the problem, develop a systematic and efficient process for gathering accurate historical information, perform a structured neurotologic examination, and provide a rational treatment approach that addresses all major contributing factors.

Multifactorial Nature of Dizziness

The three primary sensory inputs responsible for balance originate from the vestibular, visual, and somatosensory (proprioceptive) pathways. Maintenance of balance requires accurate integration of three processes: (a) appropriate detection of various environmental sensory inputs, (b) accurate central nervous system (CNS) integration of all sensory input and production of an appropriate neural response, and (c) performance of the correct muscle response for maintenance of postural control and gaze stability (Fig. 165.1). The vestibular labyrinth can be divided into the semicircular canals (SCCs) (horizontal, superior, and posterior) and the otolith organs (utricle and saccule). The primary function of the SCCs is to detect high-velocity, angular head movement and to produce a compensatory eye movement via the vestibuloocular reflex (VOR) for stabilization of visual images on the retina and maintenance of acuity during head movement. In contrast, the primary function of the otolith organs is to sense linear acceleration (including gravity) and to produce compensatory postural changes in response to transient linear movements and changes via gravity through the vestibulospinal reflex (VSR) pathways. Taken together, the VOR and VSR serve to stabilize the visual world and upright stance and ambulation, respectively.

The visual tracking and fixation pathways sense movement in the visual surround and allow the individual to respond to either slowly moving (smooth pursuit, optokinetic) or novel (saccadic) objects of interest and augment the VOR for maintenance or acquisition of desired targets. With the vestibular system acting as the "gold standard" internal frame of reference, visual inputs are interpreted in combination with vestibular cues for generation of the desired eye movement for the task at hand.

The somatosensory inputs from the feet, lower limbs, and trunk serve to orient the body to contact surfaces and respond to transient perturbations by generating reflexive corrective limb movements using the ankle joint as the primary fulcrum of movement during upright stance. These cues, along with vestibular inputs, are critical for the maintenance of upright stance and gait control. The absence of accurate vestibular cues or the transmission of incorrect cues invariably leads to poor posture control and ambulation, often resulting in falls.

The second component of balance control is sensory integration, which requires the brain to interpret and weigh all sensory inputs and generate a rapid and accurate response (Fig. 165.1). In some instances, sensory cues are in conflict or ambiguous. Under these circumstances, the brain must decide which cues are appropriate for the given situation and ignore or suppress those that have an incorrect orientation. In susceptible individuals, motion sickness can result.

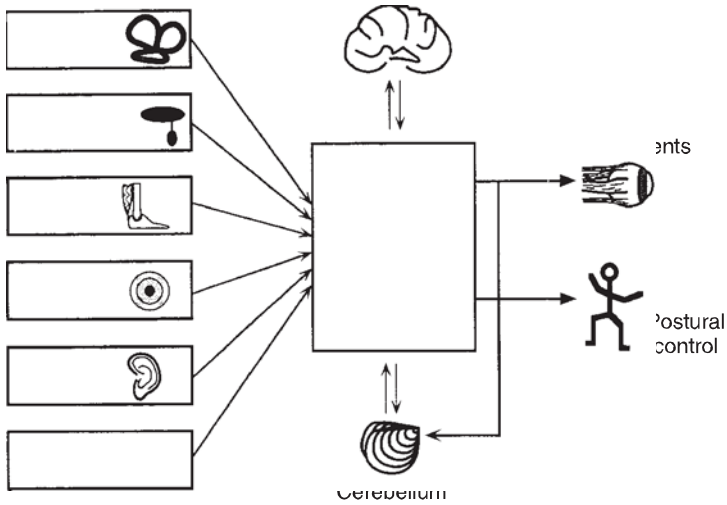

Figure 165.1 An integrated approach to the diagnosis of dizziness and imbalance. Maintaining balance requires a patient to sense the environment (via sensory afferent input), to integrate the environmental information via central processing, and to calculate the correct motor response (delivered via motor efferent output). Accurately locating the abnormality within this integrated system is crucial when a patient presents with dizziness, imbalance, or vertigo. (From Hughes GB, Pensak ML, eds. *Clinical otology*, 2nd ed. New York: Thieme Medical Publishers, 1997:44, with permission.)

The final component of posture control is generating an appropriate motor response to sensory inputs. This elaborate task requires an intact peripheral motor system and adequate musculoskeletal capability. In some cases, sensory input and central integration are intact, but inadequate motor capabilities lead to imbalance and falls. It is, therefore, important in each patient with imbalance or dizziness to decide whether or not there is a sensory deficit, a central integration problem, an inadequate musculoskeletal response, or a combination of factors leading to their symptom complex.

Importance of History

A structured and thorough discovery of all pertinent historical events is critical in the evaluation of the dizzy patient (5). In roughly 75% of cases, the history alone yields an accurate differential diagnosis, even before the physical examination or laboratory tests are performed (5). The reasons a precise history is essential are as follow: (a) Most disease processes that cause dizziness have a particular symptom pattern; (b) diseases of the inner ear and eighth cranial nerve cause distinctly different sensations than CNS, musculoskeletal, systemic, or psychogenic processes; (c) most patients are not experiencing an acute sensation of dizziness at the time of examination; and (d) the CNS has a remarkable way of compensating between episodes such that clinical examinations and laboratory findings are only seen during acute episodes or in cases of significant damage. As discussed below, development of a systematic approach to history taking allows the examiner to build a differential diagnosis even prior to performing the physical examination and further testing.

Evaluation of Sensory (Vestibular, Visual, and Somatosensory), Central Integration, and Motor Control Aspects

After obtaining a comprehensive history, the examiner then proceeds to perform a basic otolaryngologic and structured neurotologic examination. Causes of dizziness should not be overlooked at this stage and must be detected on the routine otolaryngologic head and neck examination (e.g., impacted cerumen, middle ear effusion, obstructed nasal airway, and sinus disease). Following this examination, a detailed evaluation of spontaneous and evoked eye movements, VOR and VSR functions, posture, and gait is performed. Special attention is paid to the function of each sensory input, central integration of these inputs, and the generation of an appropriate eye or trunk/limb movement for maintenance of gaze and upright stance.

Judicious Use of Laboratory Testing to Quantify Deficits

In many cases, the etiology of the patient's dizziness is clear subsequent to taking the history and performing a thorough physical examination. Further audiovestibular, radiologic, and serologic testing may be necessary to support the suspected diagnosis and to quantify the extent of the deficit prior to initiation of medical and/or surgical management. Furthermore, vestibular function tests as a whole exhibit fairly high specificity (80% to 85%), but only modest sensitivity (60% to 65%) (6). Consequently, vestibular function tests are limited in their ability to "rule out" dysfunction for most diseases affecting the labyrinth or eighth cranial nerve. It is, therefore, incumbent on the specialist who manages the dizzy patient to understand the critical role of taking a comprehensive history and performing a structured physical examination prior to ordering any further tests.

HISTORY TAKING

Methods: Questionnaire and Direct Questioning

A variety of methods exists for gathering historical information from the patient prior to the physical examination: (a) structured questionnaire mailed to the patient (see included example), (b) phone interview and verbal

Dizziness and Balance Center

Patient Name:_____ **D.O.B:**___/___/___ **Sex: M**___**F**___ **Date:** ___/___/___

The following questions refer to your feeling of dizziness. Please answer them as "yes" or "no" and fill in all blanks.

Please describe in your own words, the sensation you feel without using the word "dizzy":

_____

_____

_____

I. Do you ever have any of the following sensations?

Yes	Spinning in circles	No
Yes	Falling to one side	No
Yes	World spinning around you	No

II. The following refer to a typical dizzy spells:

Yes	Do your dizzy spells come in attacks?	No
	How often? _____	
	How long is the attack? _____	
	Date of first spell? _____	
Yes	Are you free from dizziness between attacks?	No
Yes	Does your hearing change with an attack?	No
Yes	Are you dizzy mainly when you sit or stand up quickly?	No
Yes	Are you dizzier in certain positions?	No
	Which position? _____	
Yes	Are you nauseated during an attack?	No
Yes	Are you dizzy even when lying down?	No
Yes	Have you had a recent cold or flu preceding recent dizzy spells?	No
Yes	Have you had fullness, pressure, or ringing in your ears?	No
Yes	Have you had pain or discharge in your ear of recent onset?	No
Yes	Have you had trouble walking in the dark?	No
Yes	Are you better if you sit or lie perfectly still?	No

III. The following refer to other sensations you may have:

Yes	Do you black out or faint when dizzy?	No
	Have you had:	
Yes	Severe or recurrent headaches?	No
Yes	Light sensitivity with your headaches or dizziness?	No
Yes	Any double or blurry vision?	No
Yes	Numbness in your face or extremities?	No
Yes	Weakness or clumsiness in arms, legs?	No
Yes	Slurred or difficult speech?	No
Yes	Difficulty swallowing?	No
Yes	Tingling around your mouth?	No
Yes	Spots before your eyes?	No
Yes	Jerking of arms or legs?	No
Yes	Seizures?	No
Yes	Confusion or memory loss?	No
Yes	Recent head trauma? (If yes, please explain)	No

_____

_____

_____

IV. The following refer to your hearing. Indicate which side has been affected:

Yes	Difficulty hearing in one ear?	Left	Right	Both	No
Yes	Ringing in one ear?	Left	Right	Both	No
Yes	Fullness in one ear?	Left	Right	Both	No
Yes	Change in hearing when dizzy?				No
	Have you had any of the following?				
Yes	Pain in ears?	Left	Right	Both	No
Yes	Discharge from ears?	Left	Right	Both	No
Yes	Hearing change?				No
Yes	Better?	Left	Right	Both	No
Yes	Worse?	Left	Right	Both	No
Yes	Exposure to loud noises?				No
Yes	Previous ear infections?				No
Yes	Previous ear surgery?				No
	What? _____				No
Yes	Family history of deafness?				No

V. The following refer to habits and lifestyle:

Yes	Is there added stress to your life recently?	No
Yes	Are you dizzy or unsteady constantly?	No
	Is your dizziness related to:	
Yes	Moments of stress?	No
Yes	Menstrual period?	No
Yes	Overwork or exertion?	No
Yes	Do you feel lightheaded or have a swimming sensation when you are dizzy?	No
Yes	Do you find yourself breathing faster or deeper when excited or dizzy?	No
Yes	Did you recently change eyeglasses?	No
Yes	Have you ever had weakness or faintness a few hours after eating?	No
Yes	Do you drink coffee? How much? _____	No
Yes	Do you drink tea? How much? _____	No
Yes	Do you drink soft drinks? How much? _____	No
Yes	Do you drink alcohol? How much? _____	No
Yes	Do you smoke? What? _____ How much? _____	No

Past Medical History:

Please list your current medical problems and length of illness: _____

_____

_____

_____

Please list all surgery performed and approximate dates: _____

_____

_____

_____

Please list all allergies (including drugs) and reaction: _____

_____

_____

_____

Please list all medicines you currently take (including pain medicine, nonprescription medicine, nerve pills, sleeping pills, or birth control pills). _____

_____

_____

_____

Have you had any previous testing (hearing, x-rays, head scans, etc.)? _____

_____

_____

Family History:
Any family history of:

Yes	Migraine?	No
Yes	High blood pressure?	No
Yes	Low blood pressure?	No
Yes	Diabetes?	No
Yes	Low blood sugar?	No
Yes	Thyroid disease?	No
Yes	Asthma?	No

Please list any other diseases that run in your immediate family: _____

_____

System Review:
Check all applicable symptoms:

Constitutional:			
☐ Recent weight change	☐ Fever	☐ Fatigue	☐ N/A
Eyes:			
☐ Loss of Vision ☐ Left ☐ Right ☐ Both	☐ Pain ☐ Left ☐ Right ☐ Both	☐ Discharge/Tearing ☐ Left ☐ Right ☐ Both	☐ N/A
Ear, Nose, Mouth, Throat:			
☐ Itchy ears	☐ Facial weakness	☐ Nasal obstruction	☐ Nasal discharge
☐ Nosebleed	☐ Sneezing	☐ "Stuffy" nose	☐ Snoring
☐ Loss of sense of smell	☐ Growth in nose	☐ Nasal bleeding	☐ Drooling
☐ Mouth growth, ulcer	☐ Chewing difficulty	☐ Lump in neck	☐ Dental problems/ Poorly fitting dentures
☐ Pain on swallowing	☐ Heartburn	☐ Sore throat	☐ Bleeding from throat
☐ Voice changes	☐ Breathing difficulty	☐ N/A	
Cardiovascular:			
☐ Chest pain	☐ Irregular heart beat	☐ Swelling of legs	☐ Leg pain with walking
☐ Leg pain with rest	☐ N/A

gathering of information, and (c) face-to-face interview at the time of the physical examination. The advantage of a structured questionnaire is its capability to supply comprehensive data regarding the nature of the dizziness/imbalance episodes, accompanying symptoms, additional medical conditions, medications, and lifestyle. However, such questionnaires must be simplified so that it is understandable for the patient and well organized for the practitioner to efficiently interpret the data. Moreover, these questionnaires should be completed prior to the appointment rather than hurriedly filled out in the waiting room. A well constructed and thoughtfully completed questionnaire can be a valuable tool for the examiner to review prior to the patient interview. Alternatively, a medical assistant can conduct a phone interview and record the data. The disadvantages of this approach include that this method can be more time consuming and costly, and the resulting data are less comprehensive than the data from a written questionnaire. Finally, the face-to-face interview by the physician is the most important step in confirming and/or clarifying what the patient has either written in the questionnaire or told the medical assistant by phone. Using the written questionnaire as a guide allows the examiner to ask directed questions during the interview in an efficient fashion to best understand the patient's symptom complex (Table 165.1).

Components of the History

Distinction Between Vertigo, Disequilibrium, and Light-Headedness

The first important piece of information in the history is the nature or quality of the sensation experienced during their episodes. Types of dizziness can be roughly divided into three broad categories: (a) vertigo, (b) disequilibrium, and (c) light-headedness (Table 165.1). *Vertigo* can be defined as a false sense of motion within the patient's environment and is usually described as a "spinning, whirling, tumbling, or even rhythmic rocking" feeling (7). In most instances, patients will sense that the environment is in motion around them (objective vertigo) and may describe the illusion that objects within their visual world (e.g., pictures, furniture, etc.) are actually moving in one direction or another before their eyes. In a minority of cases, the patients feel that they are in motion relative to a stationary world (subjective vertigo). In either event, the illusion of motion is distinct. Such strong sensations of environmental and/or self-motion are most often generated by a sudden asymmetry within the peripheral vestibular system (labyrinth or eighth cranial nerve) and are valuable indicators of peripheral inner ear or nerve dysfunction.

TABLE 165.1 THE HISTORY OF PRESENT ILLNESS IN A PATIENT WITH DIZZINESS

Components of the Interview	Key Historical Features
What is the character of the dizzy sensation?	Vertigo, disequilibrium, or light-headedness
What is the dizziness pattern?	Continuous or episodic
What is the time course of dizzy episodes?	Seconds, minutes, hours, days, or longer
Was there an event associated with dizziness onset?	Head/inner ear trauma, barotrauma, upper respiratory infection, ear infection, systemic illness or infection, ototoxic medication
What associated symptoms accompany the dizzy episodes?	Hearing loss, tinnitus (continuous vs. pulsatile), aural fullness, conductive hyperacusis, diplacusis, dysacusis, autophony, oscillopsia, otorrhea, otalgia, headache, facial or limb weakness, dysphagia, dysphasia, visual changes, photophobia, phonophobia, loss of consciousness, seizure
What exacerbates the dizziness?	Rapid head movement, particular head positions, increased pressure (Hennebert sign), sounds (Tullio phenomenon), hyperventilation, strong environmental stimuli (bright lights, odors, etc.), food triggers
What medications (past and present) could be involved?[a]	Antibiotics, antineoplastic, analgesics, antihypertensives, neuroleptics, antidepressants, sedatives
What is the patient's past medical history?	Migraine, endocrine (e.g., diabetes), rheumatologic, cancer, cardiovascular, systemic infections
What is the patient's past surgical history?	Focusing on otologic or brain surgery
What is the family history?	Migraine, endocrine (e.g., diabetes), rheumatologic, cancer, cardiovascular, systemic infections, genetic mutations

[a]See Table 165.2 for a more detailed discussion.

In contrast with vertigo, patients who have *disequilibrium* describe difficulty maneuvering within their physical environment often without experiencing an illusion of motion (Table 165.1). Patients with disequilibrium may use synonyms like "imbalanced, clumsy, uncoordinated, or fear of falling," and their symptoms are usually worse while standing or ambulating. A variety of CNS, peripheral neuropathic, and musculoskeletal disorders can cause disequilibrium, although slowly progressive, bilateral vestibular loss without significant asymmetry may present with this complaint.

The third category—*light-headedness*—comprises both a wide range of sensations (such as "wooziness, giddiness, feeling faint, or as if one is about to pass out") and of etiologies (including migraine, vascular, metabolic, drug-induced, endocrine, or primary psychogenic causes) (Table 165.1). Light-headedness, though, is less commonly a primary complaint of patients with damage of the peripheral vestibular pathways. Instead, light-headedness is most often comorbid with vertigo and/or disequilibrium.

Time Course

Once the nature and quality of the sensation is elucidated, the examiner then attempts to determine the duration of the symptoms (Table 165.1). The first question is whether or not the sensation is continuous or episodic and, if so, do the episodes last seconds, minutes, hours, days, or even longer. When patients complain of vertigo, this time course distinction is exceedingly valuable since the most common peripheral vestibular disease processes produce stereotypical attacks of consistent duration. For example, patients with benign paroxysmal positional vertigo (BPPV) usually complain of discrete attacks that last less than 1 minute. In contrast, patients with Ménière's disease usually describe a "spinning feeling" that can last 15 minutes to many hours. Finally, patients who develop vertigo secondary to vestibular neuritis describe attack(s) of continuous spinning lasting up to 24 hours. In patients with transient ischemic attacks involving the vertebrobasilar circulation and brainstem, attacks generally last 15 minutes, whereas brainstem infarcts and cerebellar hemorrhages exhibit acute, severe vertigo lasting hours and impact the inability to stand.

The time course of attacks in patients with disequilibrium is somewhat less stereotypical of their disease process. Frequently, patients report that symptoms persist as long as they are upright. Similarly, patients with light-headedness may have a variable symptom picture, with sensations lasting anywhere from seconds to days. Finally, patients with migraine-associated dizziness (MAD) may complain variably of all three sensations, and the duration may fluctuate from seconds to days or even longer.

Associated Events

It is crucial to elucidate associated events that occurred near the time the dizziness began, such as trauma, recent or chronic infection(s), systemic diseases (e.g., rheumatologic, autoimmune, or metabolic), or medication changes. Posttraumatic vertigo can be the result of (a) direct mechanical trauma to the head or inner ear structures (e.g., penetrating injuries damaging the inner ear, SCC dehiscence) and/or (b) barotrauma (i.e., damage caused by pressure changes). Activities associated with barotrauma may include military service with exposure to blast injuries, scuba

diving, hyperbaric oxygen treatments, straining (e.g., weight lifting or childbirth), or changes in altitude (e.g., airplane flights or driving in the mountains), especially during an upper respiratory infection that causes congestion. Posttraumatic vertigo may be due to perilymphatic fistula(s) (PLF) of the oval and/or round windows (8–11), delayed endolymphatic hydrops (12), BPPV (13), migraine, or middle ear surgery (14). Furthermore, trauma may cause a dehiscence of the superior SCC if the bone covering the canal was thin prior to the injury (15–17).

Determining a history of recent infections is important. For example, vestibular neuritis is thought to be caused by viral infection, and an upper respiratory viral prodrome may occur prior to vertigo onset (18). Other infections that can cause vertigo include herpes zoster oticus (Ramsay Hunt syndrome), suppurative otitis media, human immunodeficiency virus, syphilis, Lyme disease, and tuberculosis. Additionally, recent systemic infections or cancers may have necessitated the administration of ototoxic drugs that can cause vertigo.

Finally, it is imperative to determine if the patient also has a systemic condition including a rheumatologic, autoimmune (e.g., Wegener granulomatosis, systemic lupus erythematosus), and/or metabolic (e.g., diabetes) disease that may be associated with vertigo.

Accompanying Symptoms

In many cases, accompanying symptoms assist the examiner in determining if the site of lesion is located in the labyrinth, eighth cranial nerve, brainstem, or cortical areas (Table 165.1). Hearing loss, tinnitus, aural fullness, and vertigo strongly suggest labyrinthine involvement. Fluctuations in these symptoms may suggest Ménière's disease or posttraumatic endolymphatic hydrops. On the other hand, vertigo without hearing loss may be generated by the labyrinth (e.g., BPPV), eighth cranial nerve (e.g., vestibular neuritis), brainstem (e.g., isolated vestibular nuclei infarct), and/or cerebral cortex (e.g., migraine, seizure). Patients with superior SCC dehiscence can present with conductive hyperacusis or autophony. Conductive hyperacusis includes symptoms such as hearing one's own eye movements, one's own heartbeat, and/or the impact of one's feet during walking or running in the affected ear (17,19). Associated facial weakness suggests a lesion proximal to the labyrinth, while dysphagia, dysphasia, limb weakness, and ataxia are indicators of CNS involvement. Patients with MAD frequently complain of photophobia, phonophobia, or heightened sense of smell. Finally, loss of consciousness implies a significant perfusion failure of the cerebrovascular circulation and is not associated with primary labyrinthine or eighth cranial nerve lesions.

Exacerbating Factors

Since the vestibular labyrinth is sensitive to angular motion (turning the head), transient linear motion (sudden translations), and gravity (tipping the head and body), disorders of the inner ear are frequently aggravated by head movements and changes of the head and/or body vis-a-vis gravity (Table 165.1). Patients with vestibular disorders tend to keep their head as still as possible and avoid sudden movements. Vertigo induced by very specific head positions (e.g., rolling over in bed, or tilting the head back to rinse their hair in the shower), which lasts for seconds, suggests BPPV. In cases of bilateral and uncompensated unilateral vestibular dysfunction, patients have difficulty walking in the dark or on uneven surfaces and avoid fast head movements due to bobbing or blurring of their visual field (oscillopsia). Patients with orthostasis become more symptomatic with changes in position against gravity such as arising from a bed or chair and obtain relief by lying flat.

Patients with superior SCC dehiscence may present with sound-induced vertigo (Tullio phenomenon) or pressure-induced vertigo (Hennebert sign) (17,19). Valsalva maneuvers, coughing, or sneezing can induce vertigo or oscillopsia. Furthermore, hyperventilation (e.g., exercising) may induce vertigo in peripheral (e.g., cerebellopontine angle [CPA] tumors) or central (e.g., multiple sclerosis) lesions.

In cases with MAD, exposure to visual motion, bright lights, loud sounds, or strong odors can exacerbate dizziness. Furthermore, MAD patients can, at times, identify food triggers such as caffeine, alcohol, cheese, or citrus fruits. Changes in dietary salt intake may trigger dizziness in patients with Ménière's disease.

Medications and Comorbidity

Dizziness is a common side effect of many medications, and, in some instances, the interaction of multiple medicines is the cause of a patient's symptoms (Table 165.2). Medications causing dizziness, light-headedness, and/or auditory symptoms generally are divided into three categories: those that are (a) ototoxic, (b) affect systemic blood flow, and (c) act on the CNS. Once the drug is stopped or the dose adjusted, symptoms may reverse. However, in some circumstances, the damage may be permanent. Therefore, the examiner must query the patient not only about current medications but also about previous medication usage.

Ototoxic drugs damage the peripheral vestibular system. Ototoxicity usually results in a symmetric loss of vestibular end organ function, which disables the VOR. Thus, patients loose visual stability with head movement, resulting in oscillopsia (i.e., bobbing or jiggling of the visual field). Patients with bilateral vestibular loss present with disequilibrium and have tremendous difficulty or are completely unable to maintain balance and posture in the dark. The most common ototoxic drugs are aminoglycosides and chemotherapy agents (Table 165.2). Aminoglycoside antibiotics (e.g., streptomycin, gentamicin, neomycin, tobramycin, amikacin, kanamycin) constitute a group of natural and semisynthetic compounds used to treat aerobic gram-negative bacilli and mycobacterium. Aminoglycosides inhibit bacterial protein synthesis by binding to the

TABLE 165.2 MEDICATIONS THAT MAY CAUSE DIZZINESS

Drug Class	Mechanism	Symptoms
Ototoxic		
Aminoglycosides *Gentamicin, neomycin, tobramycin, amikacin, kanamycin*	Damages vestibular type I sensory cells, outer hair cells in the organ of Corti, and cochlear and vestibular neurons Loop diuretics and vancomycin can potentiate ototoxicity	Oscillopsia from symmetric vestibular hypofunction Vertigo from asymmetric vestibular loss, sensorineural hearing loss, and tinnitus
Antineoplastic agents *Cisplatin*	Damages vestibular hair cells, outer hair cells in the organ of Corti, stria vascularis, and spiral ligament	Same symptoms as aminoglycoside damage
Analgesic agents *NSAIDs (aspirin, naproxen, indomethacin, and ibuprofen)*	Reversible outer hair cell function changes and reduced blood flow via vasoconstriction	Reversible sensorineural hearing loss, tinnitus, and rarely vertigo
Acetaminophen/hydrocodone	Permanent hair cell damage	Rapidly progressive, permanent sensorineural hearing loss, tinnitus, and rarely vertigo
Systemic Blood Flow		
Antihypertensives *Diuretics, β-blockers, vasodilators, CCB α-adrenergic blocker*	Systemic vasodilation leading to decreased peripheral vascular resistance	Light-headedness, syncope, visual changes, and fatigue
Central Nervous System		
Neuroleptics Antidepressants *Tricyclics, MAOIs, SSRIs* sedatives	Target central dopamine, serotonin, GABA, and acetylcholine neurotransmitter pathways	Light-headedness, vertigo, and ataxia

CCB, calcium channel blocker; GABA, γ-aminobutyric acid; MAOIs, monoamine oxidase inhibitor; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRI, selective serotonin reuptake inhibitor.

30S ribosomal subunit and cause mRNA to be misread. While the use of systemic aminoglycosides is declining in developed nations due to their significant toxicities and the availability of better alternatives, aminoglycosides are still widely used in developing countries. This is because aminoglycosides are inexpensive and effective against diseases such as multidrug-resistant tuberculosis (20,21).

All aminoglycosides cause cochlear and vestibular damage that is usually permanent. However, individual aminoglycosides differ in their ability to produce cochlear versus vestibular toxicity. Gentamicin and streptomycin are primarily vestibulotoxic (22), whereas neomycin, amikacin, and kanamycin are more cochleotoxic. Aminoglycosides destroy vestibular type I sensory hair cells, outer hair cells in the organ of Corti (from cochlear base to apex), and cochlear and vestibular neurons (20,21). The perilymph and endolymph drug concentration is directly proportional to the plasma concentration, which in turn is directly related to renal clearance (23). Aminoglycosides persist in the inner ear tissue for 6 months or longer after administration (24). The ototoxic damage may be potentiated by concurrent administration of loop diuretics (e.g., ethacrynic acid and furosemide) or vancomycin. Patients with a mutation in the mitochondrial 12S ribosomal subunit (*MTRNR1*) are particularly susceptible to aminoglycoside ototoxicity. This mutation is associated with spontaneous as well as aminoglycoside-induced hearing loss even following a single dose. Interestingly, the vestibular system does not have an increased susceptibility to aminoglycoside toxicity in patients with this mutation (25). In contrast, missense polymorphisms in three oxidative stress-related genes (*NOS3*, *GSTZ1*, and *GSTP1*) have increased susceptibility to gentamicin-induced vestibular dysfunction (26).

Numerous chemotherapeutic drugs are ototoxic. The alkylating agent cisplatin (*cis*-diamminedichloroplatinum II) is the most ototoxic antineoplastic drug and is used to treat various malignancies including head and neck cancers. Cisplatin targets the outer hair cells in the organ of Corti, stria vascularis, and the spiral ligament (Table 165.2) (27). Vestibular toxicity seems to occur later than auditory toxicity. Both elderly and pediatric patients are reportedly more sensitive to cisplatin ototoxicity than other age groups (28). Patient symptoms of bilateral vestibular loss will present in the same way as aminoglycoside toxicity.

There is evidence that high-dose analgesic use is ototoxic. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as salicylates (aspirin) (29), naproxen (30), indomethacin, and ibuprofen are among the offending agents (31,32). High-dose salicylates (several grams per day) cause outer hair cell dysfunction and decreased blood flow to the inner ear via vasoconstriction, possibly mediated by antiprostaglandin activity. The result is reversible hearing loss and tinnitus (29,33,34). Other NSAIDs have similar ototoxic effects through reduction of blood flow (29). Acetaminophen/hydrocodone (e.g., Vicodin, Lortab,

and Norco) abuse has been reported to cause permanent, rapidly progressive, sensorineural hearing loss (35–38). Although less common than auditory symptoms, vestibular symptoms (e.g., vertigo or disequilibrium) caused by high-dose analgesics can occur. When vestibular symptoms do develop, their onset can even precede tinnitus (Table 165.2) (39).

Many types of antihypertensive medications can cause dizziness (Table 165.2). Examples include diuretics, β-blockers, vasodilators, calcium channel blockers, and α-adrenergic blockers. These medications result in dizziness through persistent orthostatic hypotension or, in part, by effecting CNS neurotransmitter pathways. Symptoms can include light-headedness, syncope, visual changes, and fatigue. Often these symptoms improve or resolve completely with dose adjustments.

Drugs acting on the CNS can cause dizziness (Table 165.2). The pharmacologic targets of neuroleptics, antidepressants (e.g., tricyclics, monoamine oxidase inhibitors, and selective serotonin reuptake inhibitors), and sedatives are located in the cortex or the brainstem. Several of these drug classes affect neurotransmitters such as dopamine, serotonin, acetylcholine, and γ-aminobutyric acid (GABA), which can lead to hypotension, light-headedness, vertigo, and ataxia. At therapeutic doses, Dilantin can often lead to ataxia, vertigo, and gaze-evoked nystagmus (GEN). The first step in diagnosis is obtaining a detailed medical history, including a thorough medication history, and determining the character of the dizziness. Medication side effects may be the sole offender or may be exacerbating an underlying vestibular pathology.

STRUCTURED NEUROTOLOGIC EXAMINATION

The most effective examination of the dizzy patient is a structured, stand-alone series of tests after the standard otolaryngologic head and neck examination has been completed. Common disorders such as serous middle ear effusion, nasal airway obstruction, and sinusitis can cause dizziness and must be excluded. Table 165.3 outlines the structure of the neurotologic examination for dizziness. In the following section, each test is described and the interpretation discussed.

TABLE 165.3 THE NEUROTOLOGIC EXAMINATION OF THE DIZZY PATIENT

Examination	Test Performance	Outcome	Interpretation of Clinical Finding
Spontaneous nystagmus	Static visual fixation	Nystagmus waveform, direction, effect of fixation	Peripheral: Horizontal–rotary jerk nystagmus, suppresses with visual fixation Central: direction changing, horizontal, vertical, torsional, or pendular nystagmus, enhances with visual fixation
Gaze-evoked nystagmus	<30° eccentric gaze	Nystagmus waveform, direction	Peripheral: Direction-fixed nystagmus, increases while gazing in the direction of the fast phase (Alexander law) Brainstem or cerebellum: Direction-changing nystagmus, fast-phase movement in the direction of gaze, or rebound nystagmus in neutral gaze CPA mass: Brun nystagmus (direction-changing nystagmus caused by a combination of central GEN and vestibular nystagmus)
Saccades	Alternate fixation on two stationary targets	Accuracy, conjugate movement, velocity, and initiation	Peripheral: normal. Abnormalities indicate a central etiology
Smooth pursuit	Track visual target	Smooth versus jerking eye movements	Normal in peripheral vestibular pathology. Abnormalities (e.g., catch-up saccades) indicate a central etiology
Fixation suppression	Rotate examination chair ± visual fixation	Effect of fixation on rotation-induced nystagmus	Normal fixation suppression in peripheral pathology. Failure of fixation suppression suggests central (floccular) dysfunction
Head impulse test (HIT)	Rotational head thrusts while maintaining visual fixation	Refixation saccade	Peripheral vestibular dysfunction: Refixation saccade generated with rotational head thrusts toward the weak side
Head heave test (HHT)	Linear head heaves while maintaining visual fixation	Refixation saccade	Otolith damage: Refixation saccade generated with linear head heaves toward the damaged side

TABLE 165.3 THE NEUROTOLOGIC EXAMINATION OF THE DIZZY PATIENT (*Continued*)

Examination	Test Performance	Outcome	Interpretation of Clinical Finding
Postheadshake nystagmus	Headshake	Nystagmus direction	Asymmetric peripheral damage: nystagmus (in plane of damaged canal with fast phase toward stronger ear). Central: cross-coupling of nystagmus
Dynamic visual acuity (DVA)	Visual acuity (static vs. head movement)	Visual acuity decline	Peripheral vestibular dysfunction: Visual acuity decline (>2 lines on Snellen chart)
Positional testing	Various static head positions	Nystagmus onset, direction, duration, effect of fixation	Peripheral: Severe vertigo, transient, and usually direction fixed. Removing visual fixation[a] enhances nystagmus Central: Usually asymptomatic, persistent, direction changing, and may be disconjugate. Removing visual fixation[a] improves nystagmus
Positioning testing	Head movement to various head positions (e.g., *Dix-Hallpike*)	Nystagmus latency, direction, duration, fatigability, reversal	Peripheral: see Table 165.4 for details of posterior, horizontal, and superior semicircular canal BPPV. Central: Immediate (no latency), persists >1 min, no reversal nystagmus, no fatigue, direction changing, no vertigo
Limb coordination tests	Limb coordination tests[b]	Limb coordination. Arm drift with past pointing	Peripheral (vestibulospinal): All limb coordination tests, except past pointing, are normal Past pointing: excessive arm drift toward side of peripheral lesion. Central: abnormalities in any of the tests
Gait	Tandem gait, Unterberger (Fukuda) stepping test	Gait abnormalities. Rotation with stepping	Peripheral: Abnormal tandem gait with eyes closed, rotation to side of lesion with stepping test. Central: Gait abnormalities (e.g., ataxia, shuffling, etc.)
Posture	Romberg tests	Excessive sway and fall	Peripheral: Fall on tandem and foam Romberg tests (eyes closed)
Mastoid vibration	Vibration source on mastoid	Nystagmus direction	Nystagmus in the plane of the affected canal toward the stronger ear
Malleolar sign	256-Hz tuning fork on malleolus	Conductive hyperacusis	Patient hears tuning fork vibration on side of superior canal dehiscence
Pressure-evoked eye movements	Tragal compression, pneumatic otoscopy, Valsalva maneuvers	Eye movement, vertigo	Perilymph fistula, otic syphilis, or semicircular canal dehiscence
Sound-evoked eye movements	Pure tones (≈100 dB)	Eye movement, vertigo	Perilymph fistula, otic syphilis, or semicircular canal dehiscence
Hyperventilation-induced nystagmus	Hyperventilate for 90 s	Nystagmus direction	Peripheral: excitatory nystagmus toward affected ear[c]

In CNS demyelinating diseases.
[a]Frenzel lenses and infrared video goggles remove visual fixation.
[b]Finger-to-nose, finger–nose–finger, hand rapid alternating movement test, fine finger movements, heel-to-shin, past pointing test.
[c]Hyperventilation-induced nystagmus may also occur.
BPPV, benign paroxysmal positional vertigo; CPA, cerebellopontine angle.

Equipment

Figure 165.2 illustrates the minimal equipment required for the structured neurotologic examination. Three tuning forks are used (i.e., 128, 256, and 512 Hz). The 128-Hz fork is used to assess vibrotactile sensation in the lower extremities (often reduced in peripheral neuropathy). The 256 Hz is used for the malleolar test, where patients with a third-window pathology (e.g., superior SCC dehiscence) can abnormally perceive the sound in the affected ear while the fork is placed on the ankle. The 512-Hz fork is the standard auditory stimulus for Weber and Rinne testing. The Frenzel lenses allow for ocular examination without visual fixation, which can enhance peripheral vestibular nystagmus. The pneumatic otoscope (including a Siegel speculum) is used to introduce positive and negative pressures into the external auditory canal to elicit eye movement

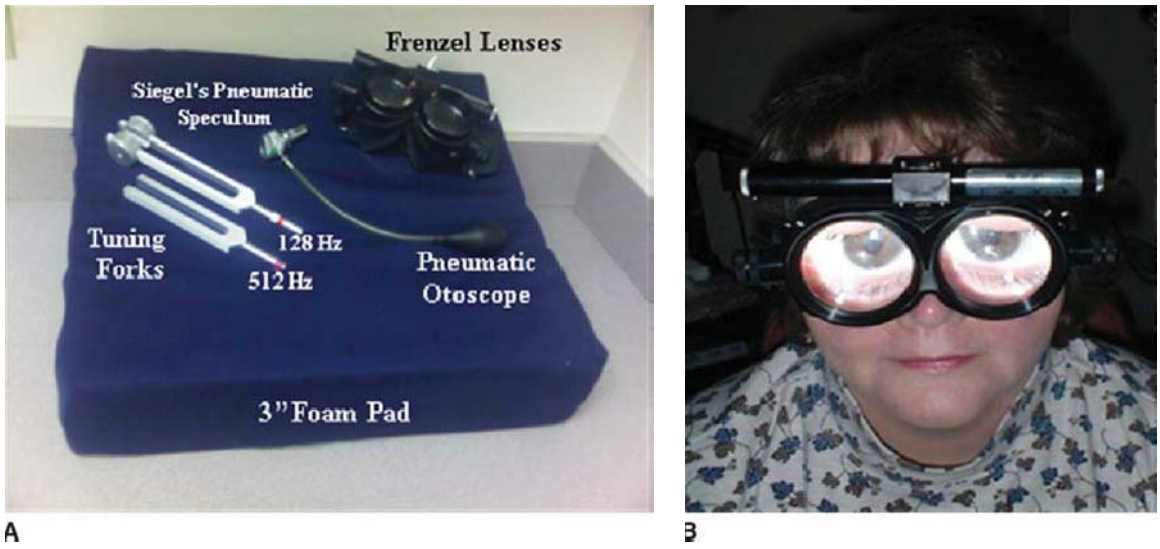

Figure 165.2 Tools necessary for a neurotologic examination of the dizzy patient. **A:** Tools include (1) tuning forks: 512 Hz for standard auditory stimulus (Weber and Rinne testing), 128 Hz to assess vibrotactile sensation in the lower extremities, and 256 Hz (not shown) for the malleolar test for third-window pathology, (2) a pneumatic otoscope including a Siegel pneumatic speculum to assess tympanic membrane mobility and to assess third-window pathology, (3) Frenzel lenses, and (4) a 3" foam pad for the foam Romberg test. **B:** Frenzel lenses provide magnification of the eyes and remove visual fixation. Peripheral vestibular nystagmus is enhanced and central nystagmus is suppressed when visual fixation is removed using Frenzel lenses.

associated with SCC dehiscence or PLF. Finally, the 3-inch foam pad is used to alter sensory input to the proprioceptive system during quiet stance with eyes closed to emphasize the use of vestibular cues for balance.

Spontaneous Nystagmus

At present, no clinical test can directly measure peripheral vestibular function. However, observing eye movements enables the examiner to gain important information regarding vestibular function. Under normal circumstances, when subjects are seated and gaze straight ahead, there is no rhythmic movement of the eyes. If, however, the eyes have a repetitive to-and-fro motion, then the term *nystagmus* is used to describe the abnormal, rhythmic oscillation. Characterizing nystagmus components often allows the examiner to infer the etiology of the eye movement and/or location of the lesion. The most common type of nystagmus is *jerk nystagmus* (e.g., *vestibular nystagmus*), which consists of a slow phase and a fast phase. Vestibular control of eye movements results in the slow phase, while the fast phase is caused by the rapid resetting of the eyes in the orbit. Jerk nystagmus is often named by the direction of the fast phase.

Test Performance

The patient is seated in an upright position and fixates on a stationary target in primary gaze position with best-corrected vision (with glasses or contact lenses in place if applicable). The patient should be queried about monovision correction because monovision can be associated with the inability to verge normally. The examiner observes the eyes for nystagmus or rhythmic refixation eye movements. The procedure is repeated under Frenzel lenses to remove target fixation. The following nystagmus characteristics are noted: (a) Waveform. Does the nystagmus have a fast phase and slow phase (*jerk nystagmus*), or are the movements equal in both directions (*pendular nystagmus*)? Is the waveform consistent or does it change? (b) Direction. In cases of horizontal or vertical jerk nystagmus, in which direction does the fast phase beat (i.e., right, left, up, or down)? For purely torsional nystagmus, the direction of movement of the upper pole of the eye is described as either a clockwise or counterclockwise rotation from the examiner's perspective. If the nystagmus has mixed components, each feature can be described (e.g., left clockwise horizontal rotary). (c) Effect of fixation. What is the relative intensity of the nystagmus with and without visual fixation? (d) Effect of gaze. What is the effect of eccentric gaze on the quality and intensity of the spontaneous nystagmus?

Interpretation

Under normal conditions, there is no spontaneous nystagmus with visual fixation and only minimal spontaneous nystagmus if any under Frenzel lenses. Vestibular nystagmus is usually direction fixed; that is, regardless of the direction of the patient's gaze, the direction of the nystagmus does not change. Unilateral, vestibular hypofunction causes an imbalance in the tonic activity of the VOR and tends to cause eye movement in the plane of the damaged SCC. This input asymmetry usually results in a spontaneous, direction-fixed, horizontal-rotary jerk nystagmus with

fast-phase movement toward the healthy ear (away from the damaged side). Removing visual fixation (e.g., placing Frenzel lenses on a patient) or gazing in the direction of the fast phase enhances the nystagmus, while gazing in the direction of the slow phase suppresses the nystagmus. This effect is called *Alexander law*. Alexander classified nystagmus as first-, second-, and third-degree nystagmus. First-degree nystagmus is the least intense and is only observed with gaze toward the fast phase. Second-degree nystagmus is more intense and is observed with the eyes in primary gaze position or when gazing toward the fast phase. Third-degree nystagmus is the most intense and is present when the eyes are in primary gaze position, gazing toward the fast phase or, gazing in the direction of the slow phase. If second- and third-degree nystagmus are present, the finding represents an acute condition or a greater disparity between the good and bad sides. Characterizing the vestibular nystagmus degree is important in determining the time course and degree of compensation for a peripheral vestibular lesion. For example, immediately after unilateral peripheral vestibular damage (e.g., vestibular ablative surgery or vestibular neuronitis), third-degree nystagmus is observed. Over the next several days, the nystagmus intensity declines passing through the stages of second- and then first-degree nystagmus. It has been postulated that the neural integrator, which is responsible for gaze-holding, is disabled when the nervous system is presented with a sudden sustained asymmetric vestibular input. The nystagmus intensity declines as the central system compensates (for a thorough description, see Ref. (40)).

In contrast, central lesions of the brainstem and cerebellum may cause direction-changing horizontal, vertical, torsional, or pendular nystagmus that may appear diminished under Frenzel lenses. Medications and alcohol may also induce a variety of nystagmus patterns. The most common form of central nystagmus is *congenital nystagmus*, which has been present since early childhood. This type of nystagmus is direction changing and waveform changing with the direction of gaze. Furthermore, there is a reduction in nystagmus with convergence, eye closure, and eccentric gaze (*null point*). Acquired forms of central nystagmus represent a failure of the central gaze-holding mechanisms in the brainstem and cerebellum or intrusions of inappropriate fast, eye movements (*saccades*) during attempted fixation. Nystagmus is reduced or absent without fixation under Frenzel lenses. *Periodic alternating nystagmus* (PAN) is a type of horizontal spontaneous nystagmus, which is also indicative of a CNS etiology. PAN is observed with the eyes in neutral gaze, and the direction of the horizontal nystagmus changes approximately every 2 minutes. Between each episode, there is often between 5 and 20 seconds where there is no nystagmus, downbeating, or upbeating nystagmus. Visual fixation has no effect on PAN and results from cerebellar pathology. It is important that the examiner observe the patient in neutral gaze for several minutes, or PAN can be missed.

Gaze-Evoked Nystagmus

GEN is a type of nystagmus that results when the eyes assume an eccentric position in the orbit. Normally, coordinated contraction of the extraocular muscles under the control of the central neural integrator is required to hold the eccentric gaze. Transient GEN is normal at extreme gaze (greater than 30 degrees from midline) and is called *end-point nystagmus*. However, any rhythmic eye movement with attempts to hold the eyes in an eccentric position within 0 to 30 degrees off midline is abnormal.

Test Performance

With the patient seated using best-corrected vision (glasses or contacts), the examiner holds his/her finger 20 to 30 degrees from the nasal root, first in the horizontal plane and then in the vertical plane, for 10 to 20 seconds in each position. The patient is asked to fixate on the examiner's fingertip. The direction and waveform of any GEN are noted. If GEN is observed with the fast phase in the direction of gaze, the examiner has the patient hold the eccentric gaze for 30 to 60 seconds, then, refixate on a fingertip held in center position. The examiner observes for a reversed fast-phase direction (*rebound nystagmus*).

Interpretation

GEN may be observed in peripheral vestibular dysfunction or in lesions of the brainstem or vestibulocerebellum. Direction-fixed GEN that increases while gazing in the direction of the fast phase (*Alexander law*) suggests unilateral peripheral vestibular dysfunction. Direction-changing GEN with fast-phase movement in the direction of gaze and/or the presence of rebound nystagmus in primary gaze indicates impairment of the brainstem or midline cerebellum (vestibulocerebellum). This observation is rarely observed in isolated peripheral vestibular injury. The vestibulocerebellum (especially the flocculonodular lobes) plays a key role in maintaining eccentric gaze. Structural lesions, degenerative conditions, CNS depressant drugs, or alcohol can give rise to GEN. However, the presence of a few transient nystagmus beats with a gaze greater than 30 degrees off midline is common and should not be confused with pathologic gaze nystagmus, which is persistent and observed at gaze angles less than 30 degrees.

Patients with a CPA mass large enough to compress the ipsilateral cerebellar flocculus may display *Brun nystagmus*. Brun nystagmus results from a combination of central (GEN) and peripheral (vestibular nystagmus). It is a gaze-dependent, direction-changing nystagmus. In primary gaze position, the patient usually does not have nystagmus. For example, if the patient has a right CPA tumor, they will have a left-beating vestibular nystagmus (small amplitude, higher frequency) with left gaze (away from the lesion). With right gaze (toward the lesion), a right-beating GEN (large amplitude, low frequency) is often observed (for a thorough description, see Ref. (40)).

Saccades

Conjugate movement of the eyes to a new visual target is generated by the command saccadic system. Saccadic eye movements involve the frontal and parietal eye fields, paramedian pontine reticular formation, medial longitudinal fasciculus, superior colliculus, and oculomotor nuclei III, IV, and VI.

Test Performance

Saccadic eye movements are examined by having the patient alternatively fixate on two stationary targets without moving their head. Using best-corrected vision and keeping the head stationary, the patient is asked to look back and forth between the examiner's nose (in neutral position) and fingertip (held 15 degrees off midline (repeat in the right and left horizontal plane as well as up and down in the vertical plane). Observe for the following eye movement characteristics: accuracy of target acquisition, conjugate movement, velocity (especially slowing), and latency of onset (initiation). Abnormalities in saccadic eye movements may be difficult to detect in the clinic examination. Videonystagmography may be necessary in order to identify subtle abnormalities.

Interpretation

Patients with peripheral vestibular pathology have normal saccadic eye movement; oculomotor abnormalities indicate ocular or CNS pathology. The midline cerebellum and fastigial nuclei control saccadic accuracy, whereas velocity, latency, and conjugate deviation are controlled by the brainstem and frontal eye fields. Abnormalities in saccadic initiation may be seen in Parkinson disease and Huntington disease. Voluntary saccades have increased latency and hypometria, whereas involuntary saccades are normal. Small-amplitude saccades are characteristic of myasthenia gravis or an abnormality in the orbit. Cortical and brainstem diseases exhibit slow saccades. Progressive supranuclear palsy (PSP) is characterized by slow vertical saccades initially as well as slow and *hypometric* (undershoot) horizontal saccades. Olivopontocerebellar atrophy (OPCA), also known as spinocerebellar ataxia (SCA), is characterized by slow saccades, especially in the horizontal direction. Inaccurate saccades (*dysmetria*) are associated with cerebellar vermis and fastigial nuclei lesions. For example, Wallenberg syndrome (i.e., lateral medullary infarction) is characterized by *hypermetria* (overshoot) toward the lesion and hypometria away from the lesion. Lesions of the frontal eye fields produce an increased latency for contralateral saccades. Pathology of the medial longitudinal fasciculus produces *internuclear ophthalmoplegia* (INO), which is frequently associated with multiple sclerosis. INO is characterized by disconjugate eye movements with slowing of the adducting eye and overshoots and/or nystagmus of the abducting eye. INO is often associated with a monocular nystagmus in the adducting eye contralateral to the lesion.

Normally, subjects can suppress saccades when visually fixating on a target. Saccadic intrusions are inappropriate movements that divert the eye from the target during attempted visual fixation. There are several types of saccadic intrusions, all of which are signs of an abnormal central process. *Square-wave jerks* are small (0.5 degrees), horizontal, involuntary saccades that take the eye off the target. After a 250-ms intersaccadic interval, a corrective saccade brings the eye back to the target. Square-wave jerks can be seen in older people. In younger individuals, square-wave jerks may be a sign of anxiety or else brainstem or cerebellar pathology. If saccades occur during visual fixation and lack an intersaccadic interval, they are termed *ocular flutter* (occur only in the horizontal direction) or *opsoclonus* (occur in all directions). Ocular flutter and opsoclonus can result from structural lesion of the pons or cerebellum, viral encephalitis, or a paraneoplastic syndrome (41).

Smooth Pursuit

Smooth pursuit is the visual tracking of moving objects caused by either target movement and/or movement of the viewer. The tracking capability of objects using foveal vision is dependent on many factors, including velocity, brightness, and predictability of the target as well as the visual acuity and age of the viewer. Smooth pursuit requires intact central optic tracts through the brainstem, visual cortices in the occipital lobes, and the flocculonodular lobes of the cerebellum. Patients must have accurate acuity (either natural or corrected) in order to perform accurate smooth pursuit. Individuals younger than 40 years of age can pursue a visual target up to 100 degrees per second with a steady decline to 60 degrees per second with advancing age. Furthermore, bright discrete targets are much easier to pursue than are dim ill-defined visual targets. The visual cortex senses relative target movement and initiates voluntary ocular tracking. The cerebellum ensures accurate pursuit by minimizing slippage of the image off the fovea. Next, the pursuit signal is compared and integrated with vestibular input in the brainstem, and a unified signal is transmitted to the oculomotor nuclei. Finally, the appropriate ocular muscle response is generated. It is clear, therefore, that abnormal ocular pursuit can arise from a variety of lesions within this complex pathway. Thus, the examiner must take many factors into consideration when testing and interpreting ocular pursuit abnormalities.

Test Performance

To assess smooth pursuit, the examiner positions his/her index finger directly in front of the patient and moves the target smoothly 20 to 30 degrees per second, first in the horizontal plane and then in the vertical plane. The testing area is restricted to the central 60 degrees of the visual field (30 degrees to the left, right, up, and down from neutral position) to avoid provoking physiologic end-gaze nystagmus. Using best-corrected vision (glasses or contacts), the patient is asked to track the examiner's finger. The examiner must assure that the patient can visualize the target clearly and is attentive to the task. The examiner performs three to

five cycles in each plane, noting the degree of ocular tracking smoothness and any corrective eye movements. After testing smooth pursuit, the examiner should test vergence. The patient is asked to follow the examiner's finger as it moves toward and away from the bridge of the patient's nose. The examiner should note if the eyes move smoothly together or if there are jerking movements.

Interpretation

In the presence of adequate visual acuity as well as appropriate target speed and velocity, smooth pursuit is generally intact in patients with peripheral vestibular disease. Occasionally, patients with acute unilateral vestibular dysfunction and spontaneous nystagmus may exhibit impaired tracking when they move their eyes in the direction of the fast phase of their spontaneous nystagmus. Patients with poor visual acuity or inattention to the task demonstrate large irregular fast eye movements (*saccades*) to catch up to the target. In central lesions, a more global failure of pursuit is evident. *Catch-up saccades* refixate the eye on the visual target in order to compensate for the pursuit deficit (*saccadic pursuit*).

Most abnormalities affect smooth pursuit symmetrically. A common cause is medication, such as anticonvulsants and sedatives as well as alcohol. The examiner should be aware that smooth pursuit performance progressively deteriorates as a patient's age increases or visual acuity declines (42–45). Furthermore, smooth pursuit is impaired by neurologic conditions such as Parkinson disease, Alzheimer disease, supranuclear degeneration, and cerebellar degeneration (41). Less frequently, abnormalities in smooth pursuit may be asymmetric. Focal central lesions may include the frontal cortex (frontal eye fields) (46), posterior cortex (47), flocculus of the cerebellum, brainstem, and thalamus (41).

Vergence eye movements are disjunctive coordinated eye movements. In other words, the two eyes move in opposite directions in response to a change in gaze. As an object moves toward the nose, each eye converges. Vergence, accommodation of the lens, and pupillary constriction are necessary for maintenance of acuity during close target viewing. As the object moves away from the nose, the eyes diverge. Vergence abnormalities can occur due to lesions of the midbrain or cerebellum or in association with medication.

Fixation Suppression of Rotation-Induced Nystagmus

Fixation suppression testing yields a qualitative assessment of visual–vestibular interaction. While classically, fixation suppression has been tested after caloric stimulation, a bedside evaluation can obtain similar information. Under normal conditions, fixation suppresses both optokinetic eye movements and vestibular-induced nystagmus. Normal fixation suppression is dependent on vision and requires normal cerebellar function.

Test Performance

To test fixation suppression, the patient is seated upright in the examination chair. Using best-corrected vision, the examination chair is unlocked and rotated up to 2 Hz without fixation. The examiner observes the eyes for nystagmus. Next, the patient fixates on his/her outstretched thumb while the chair and the visual target rotate simultaneously. The examiner observes the eyes and notes whether or not there is a decrease in the visual–vestibular nystagmus compared to rotation without ocular fixation.

Interpretation

The modulation of nystagmus invoked by rotation is a CNS phenomenon that is heavily dependent on the cerebellar flocculus. When fixation suppression is normal, the eyes remain fixated on the visual target while rotating, and no nystagmus is observed. However, if the fixation suppression is abnormal, the eyes continuously slip off the visual target during rotation due to the VOR. A refixation saccade is required to realign the eyes with the target. This refixation saccade is observed as a nystagmus. Failure of fixation suppression in the presence of adequate visual acuity is related to smooth pursuit abnormalities and implies cerebellar floccular dysfunction. Patients with peripheral vestibular abnormality have normal fixation suppression.

Head Impulse Test

The head impulse test (HIT) is a bedside technique used to detect unilateral or bilateral vestibular hypofunction. To understand this test (and many of the following tests), one must understand Ewald's three laws (48). *Ewald's first law* states that the trajectory of nystagmus generated by an SCC is in the same anatomic plane of that particular SCC (48). *Ewald's second law* is based on experiments conducted on the horizontal SCC and states that ampullopetal endolymph flow (toward the ampulla) causes a greater vestibular response than ampullofugal endolymph flow (away from the ampulla) (48,49). In other words, excitatory input is a stronger vestibular stimulus than inhibitory input (50). *Ewald's third law* is based on experiments conducted on the vertical (superior and posterior) SCCs. These experiments found that ampullofugal endolymph flow produces a greater vestibular response than does ampullopetal endolymph flow (48). Therefore, ampullofugal endolymph flow is excitatory in the two vertical SCCs.

The HIT is a method of detecting asymmetries in vestibular gain from the SCCs. In patients with profound or absent SCC function, the VOR cannot produce signals to the ocular muscles for eye stabilization during high-frequency, passive angular head rotations. Consequently, the brain must generate a refixation saccade to acquire a visual target (51,52). Saccade refixation occurs in response to passive angular head movements toward the involved ear in patients with unilateral vestibular loss. Usually, symmetrical saccadic refixation occurs in patients with bilateral vestibular loss.

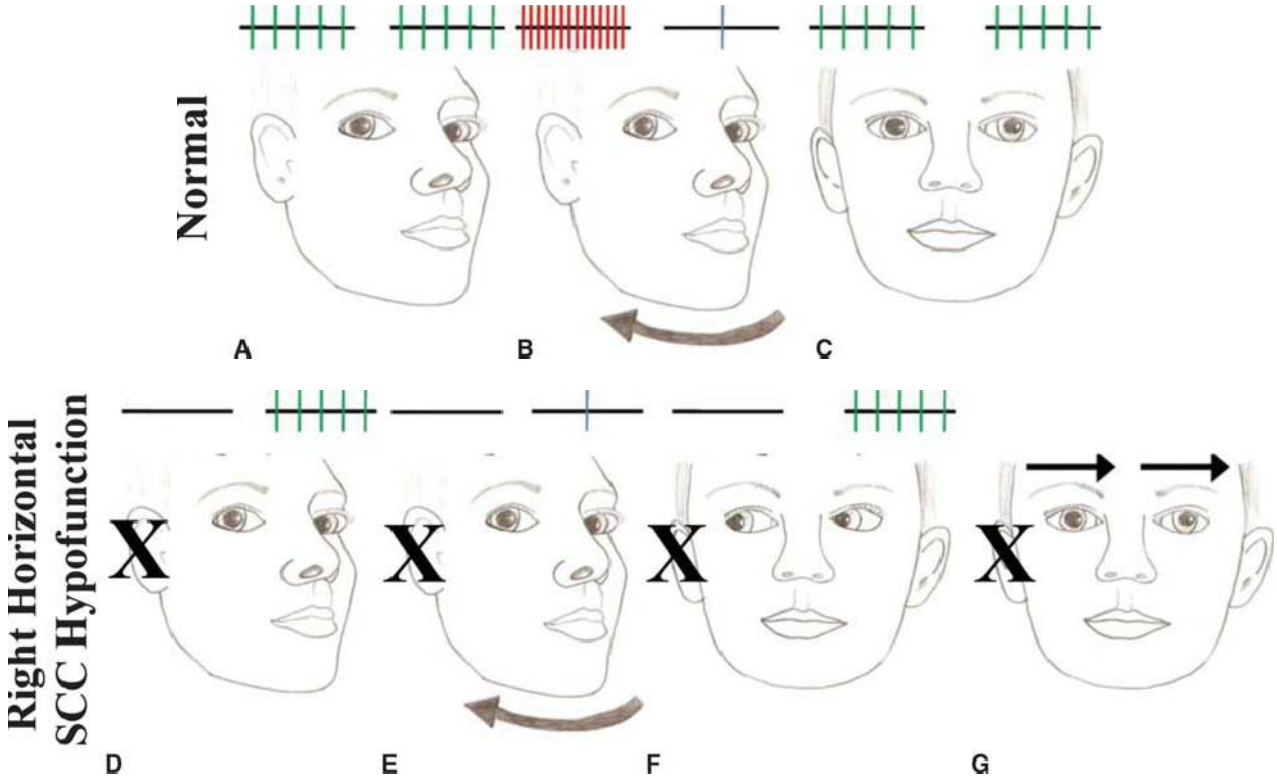

Figure 165.3 Head impulse test (HIT) in normal and unilateral vestibular dysfunction. The stages of the HIT are exemplified in a normal subject (**A–C**) and in a patient with right horizontal SCC hypofunction (**D–G**). The test begins with the patient's head at 30 degrees off midline while the patient fixates on the examiner's nose (**A, D**). **A:** In the normal subject at rest, the primary afferents of both horizontal SCCs (*green*) fire at a resting basal rate. Since the input is symmetric, the brainstem detects no motion. **B:** In the normal subject, the examiner thrusts the head rapidly (greater than 200 degrees/s or greater than 2,000 degrees/s^2) to the midline (from **left** to **right**). The discharge rate of the HSCC afferents ipsilateral to the velocity vector increases (*red*, **right**). The discharge rate of the HSCC afferents contralateral to the velocity vector decreases (*blue*, **left**). With an intact VOR, the brainstem detects asymmetric input, and the eyes are driven contralateral (**left**) to the higher firing rate (*red*, **right**). **C:** Visual fixation is maintained throughout the HIT, and the HSCC afferents return to their basal firing rate. **D:** When one labyrinth is damaged (indicated with an X), the firing rate of the right afferents decreases. **E:** The head is thrust toward the damaged side (**left** to **right**). Although the firing rate in the healthy HSCC afferents (*blue*, **left**) decreases compared to the resting position, the rate is higher than that of the right damaged side. **F:** Therefore, the eyes are driven contralateral to the healthy side and ipsilateral to the damaged side (**right**). **G:** In order to reset visual fixation, a saccadic eye movement is necessary. Abbreviations: HIT, head impulse test; HSCC, horizontal semicircular canal.

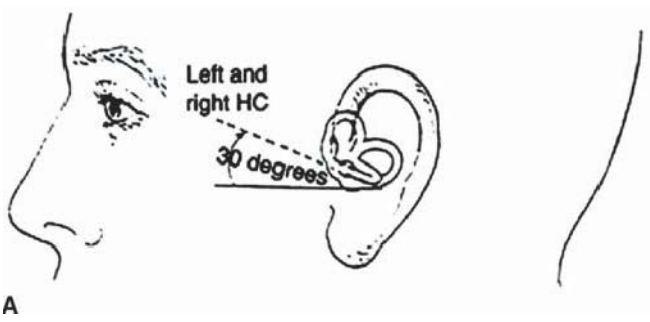
However, recent studies have shown that some bilateral vestibular loss patients have covert corrective saccades (53,54). Covert saccades are small corrective saccades that occur during the actual head movement toward their affected side. These small covert saccades are difficult for the examiner to detect with their naked eye. Therefore, eye movement recordings are required to detect the abnormality (53,54). This HIT can be performed in all three canal pair orientations and has been a significant addition to the neurotologic examination in the office (51,52,55).

Test Performance

The patient is instructed to fixate on the examiner's nose while the head is impulsively and unpredictably moved 20 to 30 degrees in one direction (Fig. 165.3). The examiner observes for any indication of ocular globe slippage off the target. The velocity of the head movement must exceed 200 degrees per second, and the acceleration must exceed 2,000 degrees per square second in order to exceed smooth pursuit capacity and fully inhibit the contribution of the contralateral ear for stabilization. To avoid neck injury, it is advisable to start at slower speeds and gradually increase to the desired velocity. The HIT is best performed in the plane of paired canals (Fig. 165.4). If the horizontal SCCs canals are being tested, the head is tilted forward 30 degrees (Fig. 165.4). Hence, the movement is in the horizontal (yaw) plane, causing ampullopetal stimulation of the canal on the same side as the movement and ampullofugal inhibition of the opposite canal (Fig. 165.3). It is desirable to move the head from an eccentric position back to midline rather than from midline to the side in order to minimize patient resistance and potential neck strain. To test the vertical canals, the examiner aligns the paired canals, right anterior (superior) and left posterior (RALP) or left anterior



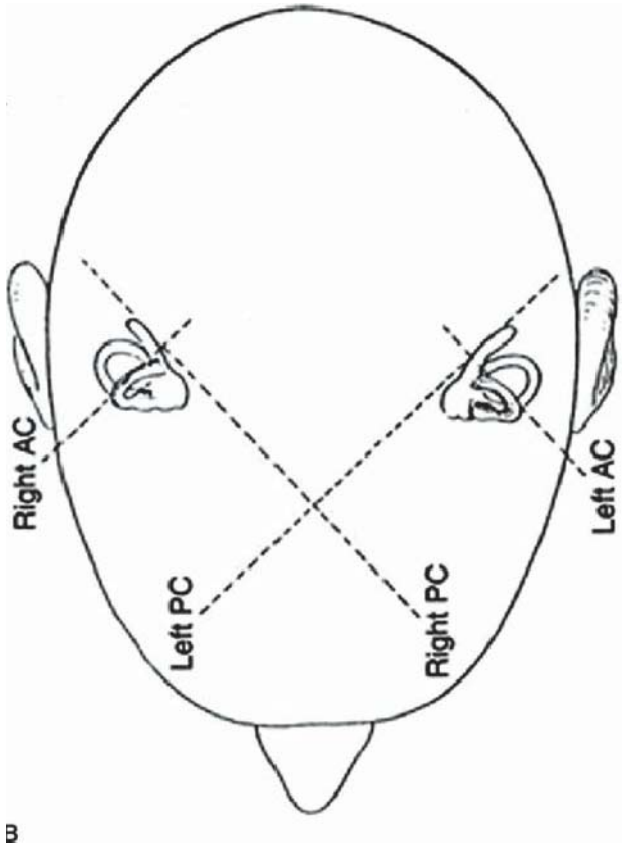


Figure 165.4 Orientation of the semicircular canals (SCCs) in the temporal bone. **A:** The horizontal SCCs are coplanar with one another and tilted 30 degrees to the horizontal plane. **B:** The vertical canals are aligned such that the anterior (superior) SCC on one side is coplanar with the posterior SCC on the other side. In other words, the right anterior (superior) and left posterior (RALP) SCCs are coplanar, and the left anterior and right posterior (LARP SCCs are coplanar. Abbreviations: AC, anterior canal; HC, horizontal canal; PC, posterior canal. (Adapted from Goebel JA (ed.). Practical anatomy and physiology. Chapter 1. In: *Practical Management of the Dizzy Patient*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008: 4).

and right posterior (LARP) (Fig. 165.4). HIT testing of the vertical canals involves head movements in the corresponding planes. In other words, to test the right anterior SCC, the head is turned 45 degrees to the left, and the head is thrust downward for ampullofugal stimulation. To test the left posterior SCC, the head is turned 45 degrees to the left, and the head is thrust upward causing ampullofugal stimulation (52,56). The examiner notes whether the eyes remain fixated on the target or whether the eyes travel with the head during the maneuver, and a *corrective saccade* is generated in order to refixate on the target. In general, the test is repeated 5 to 10 times to document repeatable fixation failure.

Interpretation

In healthy subjects, visual fixation is maintained during rapid head impulses, and no corrective saccades result. In cases of unilateral SCC dysfunction, head movement in the plane of the affected canal toward the lesioned side is accompanied by a repeatable eye slippage and corrective saccade in the opposite direction as the head movement. The observation of eye movement during the maneuver is a sign of decreased or absent neural input from the ipsilateral ear to the VOR. Reduced neural input results in little or no input to the VOR during rapid contralateral head movement, and the contralateral ear cannot supply enough neural activity to stabilize gaze. In such instances, the eye travels with the head during the high-velocity movement, and a refixation saccade is necessary to refoveate the target. Bilateral refixation movements are seen frequently in cases of ototoxicity. In rare instances of a hyperactive VOR response, a corrective saccade is generated in the same direction as the head movement. In other words, the strength of the VOR response was excessive during rotation, and a corrective saccade was required to refixate the eye on the target. A positive HIT in the presence of acute vertigo and spontaneous nystagmus is suggestive of a peripheral rather than central etiology.

Head Heave Test

The otolith–ocular reflex stabilizes the retinal image by generating compensatory eye movements in response to linear head acceleration. The *head heave test (HHT)* is used to evaluate the translational VOR (57,58). The HHT is a variant of the HIT, although in this case, the HHT is used to assess utricular dysfunction (57,58).

Test Performance

For the HHT, the examiner places his/her hands over the sides of the patient's head. The patient is instructed to look at the examiner's nose, and the examiner imposes a series of quick, high-acceleration, linear, translational "heaves" along the interaural axis. The head is moved from a right lateral to midline position and then from a left lateral to midline position. Training and skill are essential to assure patient safety. The direction of refixation saccades is noted.

Interpretation

As with the HIT, in the healthy subject, the eyes remain fixed on the visual target. In a patient with unilateral utricular dysfunction, a catch-up saccade is noted during the HHT in the direction of the damaged side. This examination is difficult to perform, and there are some safety concerns as a bedside examination. However, delivering linear force via a sled in the testing laboratory offers a more practical solution and may yield information regarding otolith dysfunction (58,59).

Skew Deviation and Ocular Torsion Reaction Test

Skew deviation is a vertical misalignment of the eyes, which results from asymmetric activity along the peripheral (60–62) or central (63) pathways mediating the otolith–ocular reflex (64). Skew deviation often presents as vertical or torsional diplopia. First, the examiner must rule out that the ocular misalignment is due to extraocular muscle palsies.

Test Performance

The *alternate cover test* is used to detect skew deviation. The examiner asks the patient to fixate on a visual target and then covers one eye. The examiner then uncovers that eye and covers the contralateral eye, observing for a vertical refixation eye movement indicating a vertical misalignment.

Interpretation

In the normal condition, the eyes do not move or deviate spontaneously in the vertical plane. However, if there is skew deviation, vertical corrective saccades will occur during pursuit. Skew deviations resulting from otolith–ocular imbalance do not usually vary with eye position. Ocular tilt reaction (OTR) is an eye-head postural reaction consisting of head tilt (ear to shoulder), skew deviation, conjugated eye cyclotorsion, and alteration of vertical perception. OTR can be caused by peripheral vestibular lesions (62,65) or central lesions (63). The head usually tilts ipsilateral to the lower eye. Peripheral vestibular and vestibular nuclear lesions result in a skew deviation with the lower eye ipsilateral to the lesion (60–62,65).

Postheadshake Nystagmus Test

During head shaking, the vestibular labyrinths send neural input to the brainstem. As soon as head shaking ceases, this stored input is discharged over a short period of time (10 to 20 seconds). Unilateral damage to the peripheral vestibular organs leads to asymmetric input and discharge resulting in nystagmus. Clinical head-shaking nystagmus is useful in detecting asymmetric peripheral vestibular lesions (66–68) or asymmetric central lesions of the velocity storage mechanism.

Test Performance

To test for head-shaking nystagmus, the patient's head is tilted forward 30 degrees, and the head is either passively or actively rotated in the horizontal plane at a high frequency (2 Hz), low amplitude (20 to 30 degrees) for 20 seconds (Fig. 165.5). Then, the head is brought to an abrupt stop, and the examiner observes for the presence and direction of any postheadshake nystagmus. To avoid fixation, the

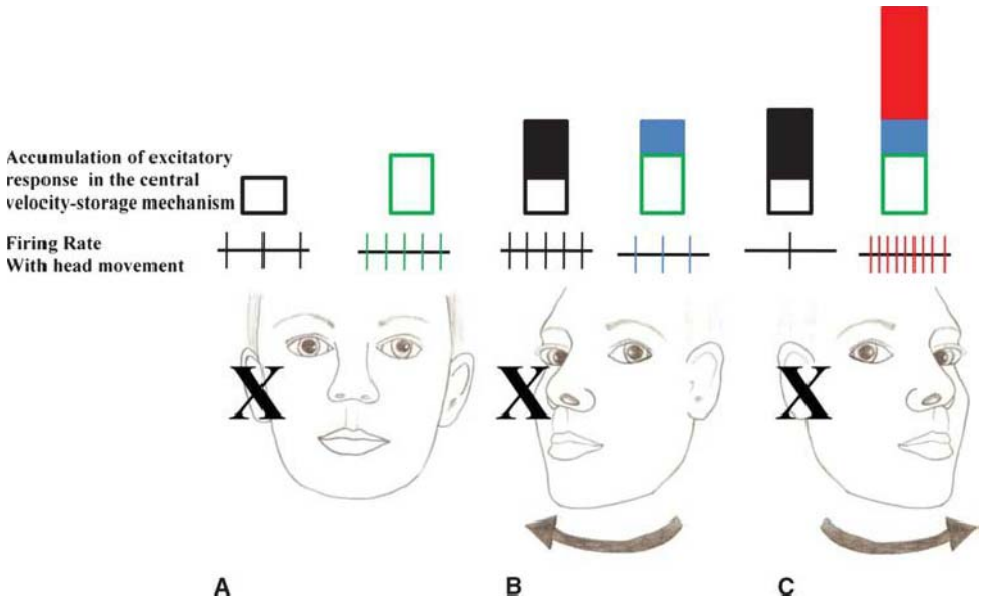

Figure 165.5 The postheadshake nystagmus test in a patient with right labyrinthine hypofunction. **A:** When the head is stationary, the asymmetry in basal firing rates between the healthy labyrinth (**left**, *green*) and the hypofunctioning labyrinth (**right**, *black*) is minimal. **B:** With head turns toward the hypofunctioning labyrinth (**right**, *black*), a weaker-than-normal excitatory response is elicited. The firing rate of the healthy labyrinth decreases (**left**, *blue*). **C:** Turning the head toward the healthy labyrinth (**left**, *red*) produces a normal excitatory response on the left. Each head rotation amplifies the asymmetry, and the activity accumulates in the central, velocity-storage mechanism. Following head shaking, stored activity is discharged from the velocity-storage center, and nystagmus results.

use of Frenzel lenses is preferred. The maneuver may be repeated in the vertical direction.

Interpretation

Postheadshake nystagmus is considered a pathologic sign of vestibular input asymmetry in the plane of rotation (66–68). If the input from the two vestibular labyrinths are symmetric (in the case of either a normal subject or an individual with symmetric, bilateral damaged), the stored vestibular activity that is discharged will cancel one another, and no nystagmus will occur. However, if the input from the vestibular labyrinths is asymmetric during head shaking (i.e., asymmetric damage to the vestibular labyrinths), then the central circuits will discharge asymmetrically, resulting in a burst of nystagmus (Fig. 165.5). Typically, a peripheral side is identified with the slow phase of nystagmus directed toward the "weaker" or abnormal ear and the fast phase directed toward the better ear. A smaller amplitude reversal of nystagmus direction is sometimes observed. Postheadshake nystagmus is not observed during an acute unilateral vestibular hypofunction because the central vestibular velocity storage system is temporarily disabled. Interpreting head-shaking nystagmus with the affected ear in Ménière's disease can be confusing as the direction depends on the excitation, paresis, or recovery phase of vestibular function following an attack. Central vestibular lesions may cause inappropriate cross-coupling of nystagmus, usually resulting in a prominent vertical nystagmus after horizontal head shaking. Signs of central etiologies can also include prolonged nystagmus and disconjugate nystagmus.

Dynamic Visual Acuity (DVA)

Maintenance of gaze stability during head movement is a complex interaction between the VOR, foveal smooth pursuit, optokinetic stimulation of the peripheral retina, and the cervico-ocular reflex. At low frequencies and peak velocities, the central oculomotor mechanisms are dominant. However, at higher frequencies and velocities, the VOR becomes the primary mechanism for maximizing visual acuity by limiting retinal slip. Standard tests of vestibular function (e.g., caloric and rotational stimulation) are useful to document deficits in low-frequency, horizontal, SCC VOR function. These tests, though, fail to assess VOR contribution to gaze stability that take place at higher frequencies and within the range of everyday head movements (1 to 4 Hz). Over the past few years, dynamic visual acuity testing (DVAT) has been developed and studied for the purpose of determining gaze stability during head movements at higher frequency (greater than 2 Hz) and peak velocity (greater than 120 degrees/s) (69–78). The DVAT compares the relative loss of visual acuity between head-still and head-moving conditions (measured in logarithmic minimal angle of resolution or logMAR). This calculation is accomplished by measuring the change in size of a visual target that a subject can accurately recognize from the resting condition (static visual acuity) to the head movement condition. The utility of the DVAT has been well documented in patients with unilateral vestibular dysfunction or bilateral vestibular loss as well as in the elderly (72,74,76,79,80).

Test Performance

With best-corrected vision, visual acuity is measured at rest using the Snellen eye chart. Visual acuity is again measured during passive horizontal head oscillations at 2 Hz. The change in visual acuity is determined. This test can also be conducted in the vertical (pitch) plane.

Interpretation

DVA is also referred to as the "dynamic illegible E test" (DIE) (71). An acuity decrease of more than two lines on the Snellen eye chart is abnormal. Excessive retinal slippage during head movement is a sign of vestibular dysfunction. In the clinical examination, the most frequent etiology is bilateral vestibular loss related to ototoxicity or aging. Poorly compensated, unilateral dysfunction can also cause loss of DVA. Nonetheless, using clinical testing, it is more challenging to identify a unilateral abnormality while simultaneously assessing DVA. During DVA assessment, it is important that the examiner shake the patient's head continually, avoiding pauses or slowing. A pause enables the patient to see the target and unconsciously attempt to compensate for their dysfunction.

Positional versus Positioning Testing

Nystagmus and vertigo can be induced by certain head postures (positional) or head movement in a specific trajectory (positioning). In other words, *positional nystagmus* is a nystagmus induced by a static head position in space. *Positioning nystagmus* is induced by the actual movement of the head from one position in space to another. The goal of positional and positioning testing is to aid in vestibular lesion localization.

Positional Testing Examination

Positional testing involves observing the eyes for nystagmus in various static head positions with and without visual fixation. Observe the eyes for at least 30 seconds in each of the following head positions: upright looking straight ahead, supine, right ear down, and left ear down. If positional nystagmus is present, it will occur approximately 30 seconds after the new head position is assumed, and the effects of positioning head movement (positioning nystagmus) have waned. The examiner should note the nystagmus direction, effect with and without visual fixation, and if it is persistent and sustained. Removing visual fixation (Frenzel lenses or infrared video goggles) worsens peripheral positional nystagmus, but central positional nystagmus improves or stays the same. Technically, true BPPV is a positioning nystagmus and occurs in the plane of the canal that is stimulated, whereas central positional nystagmus may beat in the same direction regardless of head position.

Positional Testing Interpretation

Positional nystagmus can be found in both central and peripheral pathologies. Central positional nystagmus is usually asymptomatic, persistent, and may be disconjugate. Peripheral positional nystagmus is associated with severe vertigo, transient, and usually direction fixed. A central lesion is the most likely etiology when positional nystagmus is purely vertical (up or down) or purely torsional, and visual target fixation fails to suppress nystagmus.

Positioning Testing Examination

Positioning testing is the evaluation of nystagmus in response to head movement. Positioning testing can also help distinguish central from peripheral etiologies, determine which ear is damaged, and localize the involved SCC. To perform positioning testing, the eyes are observed as the head is moved into various positions: upright, supine, right ear down, and left ear down. Preventing visual fixation (Frenzel lenses or infrared video goggles) may enhance peripheral positioning nystagmus and may diminish central positioning nystagmus. The following five nystagmus characteristics should be noted during head positioning: (a) latency, (b) direction, (c) habituation (duration), (d) fatigability (decreased nystagmus on repeated maneuvers reflects adaptation), and (e) reversal upon rising to a sitting position.

BPPV is a positioning nystagmus. The most common positioning maneuver is the Dix-Hallpike test, which is used to identify posterior canal BPPV. In other words, does BPPV indicate positional or positioning vertigo? Are the terms interchanged? (Fig. 165.6). While the patient is in a sitting position, the examination chair is unfolded, and the patient's head is turned 45 degrees toward the side to be tested. The patient's head is rapidly moved in the plane of the posterior SCC to a head-hanging, slightly extended position (120 degrees from the upright position). This position is held for 30 seconds. While keeping the head

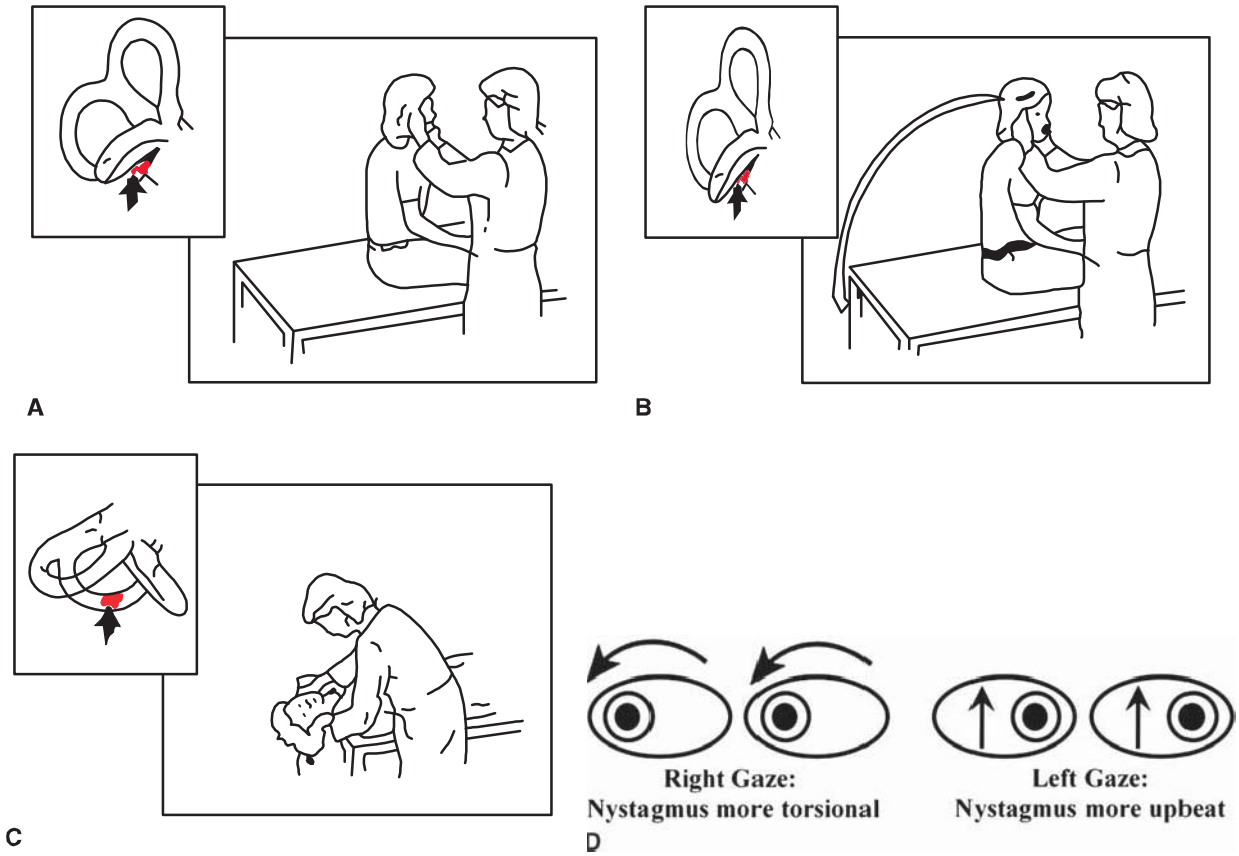

Figure 165.6 The Dix-Hallpike maneuver for diagnosing posterior SCC BPPV. The *arrow* in (**A–C**) points to the otolith debris in the right posterior SCC. **A:** While the patient is in a sitting position, the examination chair is unfolded, and the patient's head is turned 45 degrees toward the side to be tested (*right*). **B:** The patient's head is rapidly moved in the plane of the posterior SCC to a head-hanging, slightly extended position (120 degrees from the upright position). **C:** This position is held for 30 seconds, and the eyes are observed for latency, direction, duration, and fatigability of nystagmus. While keeping the head turned 45 degrees, the patient is brought back to an upright position and held for 30 seconds while the eyes are observed for reversal nystagmus. **D:** The arrows indicate the quick phase of the resulting upbeat geotropic–torsional nystagmus. With right gaze, the nystagmus is more geotropic–torsional. With left gaze, the nystagmus is more upbeat. (Adapted from Leigh RJ, Zee DS (eds.). Diagnosis and management of vestibular disorders, Chapter 11. In: *The Neurology of Eye Movements.* Oxford: Oxford University Press, 2006:572–573.)

turned 45 degrees, the patient is brought back to an upright position and held for 30 seconds while observing the eyes for nystagmus. This maneuver is then repeated on the contralateral side (Fig. 165.6). The examiner may need to perform a modified positioning maneuver in order to induce peripheral positioning nystagmus caused by horizontal SCC BPPV (81). In this maneuver, the patient is placed into the supine position, followed by turning the patient's head and body 90 degrees to the right side, back to supine, and then turn 90 degrees to the left side (82).

Positioning Testing Interpretation

BPPV is the most common cause of peripheral positioning nystagmus. BPPV is characterized by a sudden onset of episodic vertigo lasting up to 1 minute and is induced by head movement in certain positions. BPPV is caused by two mechanisms: canalithiasis (free-floating otolith debris in the endolymphatic space) or cupulolithiasis (otolith debris attached to the cupula of the SCCs) (83). The posterior SCC is affected in more than 90% of cases due to its gravity-dependent position. The horizontal SCC accounts for 6% to 8% of cases, while the superior SCC is rarely affected (less than 1%) (84,85).

For BPPV of the posterior SCC, a positive response is elicited when the head is turned toward the affected side, and the ear is positioned toward the ground. The resulting nystagmus is upbeating, geotropic torsional (upper pole of eye toward the ground). The nystagmus has a brief latency (5 to 20 seconds), less than 30 seconds duration, fatigability with repeated positioning, and in some instances, reversal nystagmus upon returning to an upright position (Table 165.4) (83). The reversal nystagmus is a downbeating, ageotropic-torsional (upper pole of eye away from the ground) nystagmus. Throughout the test, the patient is to report any vertigo sensations, which usually accompany BPPV. Vertigo without observed nystagmus may still provide a clue to the offending side and involved SCC. A positive Dix-Hallpike maneuver is diagnostic for posterior canal BPPV. Mastoid vibration may help move the otolithic debris out of the affected canal. In contrast, central positioning nystagmus is usually immediate (no latency), persists longer than 1 minute, does not produce a reversal nystagmus, does not fatigue, is direction changing, and is not usually accompanied by vertigo.

TABLE 165.4 BPPV OF THE POSTERIOR, HORIZONTAL, AND SUPERIOR SEMICIRCULAR CANALS

	Posterior	Horizontal	Superior
Incidence	90%	6–8%	<1%
Latency	5–20 s	0–3 s	Variable
Duration	<30 s	Variable	Variable
Direction	Upbeating, geotropic–torsional	Horizontal (geotropic or ageotropic)	Downbeating, ageotropic–torsional
Fatigability	Yes	Variable	Yes

Abbreviation: BPPV, benign paroxysmal positional vertigo.

BPPV can involve the horizontal SCC and may be spontaneous or result from a repositioning maneuver of the posterior SCC (86–88). Depending on the location of the debris within the horizontal SCC, the pattern of nystagmus is either horizontal geotropic (toward the ground) or horizontal ageotropic (away from the ground). If the debris is free-floating in the non-ampullated end of the right horizontal SCC (canalolithiasis), when the right ear is down, the debris flows toward the ampulla (ampullopetal). This results in a strong, horizontal geotropic right-beating nystagmus. When the right ear is up, the debris flows away from the right ampulla (ampullofugal), resulting in a weaker horizontal left-beating geotropic nystagmus. In contrast, if the debris is caught in the ampullated end of the right horizontal SCC (cupulolithiasis), when the right ear is down, the debris flows away from the ampulla. The result is a horizontal ageotropic left-beating nystagmus. When the right ear is up, the debris flows toward the ampulla, producing a stronger horizontal ageotropic right-beating nystagmus.

Therefore, how does the examiner decide which horizontal SCC contains the otolithic debris? In general, geotropic nystagmus is stronger when the lesioned ear is placed downward. However, when the nystagmus is ageotropic, the stronger nystagmus response occurs when the lesioned ear is placed upward. Additionally, both canalithiasis (free-floating debris) and cupulolithiasis (debris caught on the cupula) can occur in horizontal SCC BPPV. In canalithiasis, movement of the free-floating debris in the affected ear causes a more transient nystagmus, whereas with cupulolithiasis, the nystagmus duration is longer (30 to 60 seconds) (Table 165.4).

The bow and lean test (BLT) can also be used to distinguish which side contains the otolithic debris in horizontal SCC BPPV (89,90). From a seated position, the patient tips the head forward in a "bow" position and then backward into a "lean" position, and the resultant nystagmus in each position is noted. In right horizontal SCC canalolithiasis, during the bow position, the debris will fall with gravity toward the ampulla, resulting in a strong right-beating (ipsilesional) horizontal nystagmus. Conversely, when the patient tips the head backward, the debris now flows away from the ampulla, producing a weaker left-beating (contralesional) horizontal nystagmus. The opposite is true for canalolithiasis, where the nystagmus is directed toward the affected ear in the lean position and away from the affected side in the bow position.

Superior SCC BPPV is rare. Otolithic debris does not usually enter the SCC due to its anatomic position. In superior SCC BPPV, when the affected ear is away from the ground, a downbeating, ageotropic-torsional nystagmus results (Table 165.4) (91–93). However, debris in the downmost posterior SCC moving toward the cupula can produce an identical nystagmus pattern to that of the uppermost superior SCC. Therefore, special care must be taken to avoid confusing the two types.

Limb Coordination Tests

Examining limb coordination provides the examiner with important clues needed to diagnose and exclude central lesions of the cerebellum and brainstem (Table 165.5). Peripheral vestibular lesions will not cause limb coordination abnormalities. In order to examine limb coordination, the patient is observed performing a series of tasks. The right and left extremities are examined separately.

Test Performance

For the *finger-to-nose test*, the examiner asks the patient to close his/her eyes, place one arm in full horizontal arm extension, and then touch his/her own nose with the index finger of the extended hand. For the *finger–nose–finger test*, the patient should alternate touching the examiner's finger and his/her own nose. As the patient touches their nose, the examiner quickly moves their finger to a new horizontal position. This test assesses the patient's ability to accurately judge the position of a target. For the *hand rapid alternating movement test*, the examiner asks the patient to alternate hand pronation and supination by tapping the back of the hand on the thigh and then the front of the hand on the thigh in a rapid succession. To assess *fine finger movements*, the examiner asks the patient to touch their own thumb to each of their four fingers on the same hand in rapid sequence. To test lower limb coordination, the examiner can use the *heel-to-shin test*. The patient is asked to fully extend their right leg and place their heel on the floor. The patient smoothly moves the heel of the left foot along the shin of the extended right leg. The test is repeated with the left leg extended. During each of the above tests, the examiner observes for dysmetria or dysrhythmia. For the *past pointing test*, the patient is asked to extend both arms and point to the ceiling with both index fingers. With eyes open, the patient brings the arms down into the horizontal position to touch the examiner's index fingers. This test is repeated with the patient's eyes closed. The examiner notes if he/she observes excessive drift of the arms toward the right or the left.

Interpretation

The presence of limb dysmetria or dysdiadochokinesia is a useful indicator of cerebellar disease, which may or may not accompany midline or vestibulocerebellar oculomotor dysfunction. Patients with peripheral vestibular dysfunction will not display limb coordination abnormalities. If abnormalities are noted on the limb coordination examination, the patient should undergo imaging and evaluation by a neurologist. The past pointing test assesses upper extremity tonic balance. This test is considered a bedside vestibulospinal test. While excessive drift of the extremities to the right or to the left may indicate a cerebellar (particularly a vestibulocerebellar)

TABLE 165.5 SYMPTOMS AND PHYSICAL EXAMINATION FINDINGS OF PERIPHERAL VERSUS CENTRAL NERVOUS SYSTEM DISEASE

	Peripheral Vestibular Dysfunction	Central Nervous System Disease
Symptoms	Recurrent episodes of vertigo	Disequilibrium, imbalance, or vertigo
	No additional neurologic symptoms	Associated neurologic symptoms
Physical examination findings	Horizontal–rotary jerk nystagmus	Direction-changing, horizontal, vertical, torsional, or pendular nystagmus
	Nystagmus in the axis of dysfunctional SCC	Gaze-evoked nystagmus or rebound nystagmus
	Nystagmus suppressed by visual fixation	Nystagmus enhanced by visual fixation
	Nystagmus pattern follows Alexander law	
	Normal oculomotor tests[a]	Abnormal oculomotor tests[a]
	Positive head impulse test: unilateral or bilateral	Saccadic pursuit
	Positive head heave test	Dysmetric, disconjugate, slow, delayed saccades
	Positive postheadshake nystagmus tests	Postheadshake nystagmus tests: cross-coupling nystagmus[b]
	Reduced dynamic visual acuity	
	Positive positioning tests (e.g., Dix-Hallpike)[c]	Atypical positioning nystagmus
	Positive past pointing test	Limb incoordination, dysmetria, or dysdiadochokinesia
	Positive Unterberger (Fukuda) stepping test	Gait abnormalities (e.g., wide-based, shuffling, ataxic)
	Reduced stability: tandem and foam Romberg test	Failed Romberg stance
	Positive mastoid vibration test	
	Positive Valsalva maneuver tests	
	Positive tragal compression test	
	Positive pneumatic otoscopy test	
	Positive malleolar sign	
	Positive hyperventilation-induced nystagmus test	

SCC, semicircular canal.

[b]Cross-coupling nystagmus: purely vertical nystagmus following horizontal headshakes.
[c]See Table 165.4 for more detail.

lesion, this finding is also indicative of vestibular system abnormalities. The lesion may involve either the peripheral or central vestibular system. Further evaluation is warranted.

Gait and Posture Tests

Three sensory inputs are vital for maintaining balance: (a) visual, (b) somatosensory (proprioception), and (c) vestibular. These inputs are integrated in the CNS, and the appropriate motor commands are provided to the periphery in order to maintain balance. When one of the three sensory inputs is compromised, a patient must rely on the other two inputs to maintain equilibrium. Gait and posture tests are designed to identify the location of the abnormality affecting balance.

Test Performance

The examiner first observes the patient's gait when walking into the examination room. Discrepancies with later examination observations should be noted. For the *simple gait* test, the patient is asked to walk 50 feet down a hallway, turn rapidly, and walk back without touching the walls. The examiner observes for initiation of movement, change in gait tempo/direction, stride length, arm swing, stance width, missteps, veering/deviations, shuffling, sway, ataxia, and signs of muscle weakness or skeletal abnormality (kyphoscoliosis, limb asymmetry, and limp). For the *tandem gait test*, the patient steps heel to toe in a tandem manner across the room. With the eyes open, this test assesses cerebellar function. With the eyes closed, the tandem gait better assesses vestibular function since the CNS is more reliant on the vestibular system in the absence of visual information.

The *Unterberger (Fukuda) stepping test* is used to gain insight into the vestibulospinal function (94,95). The patient is asked to march in place with eyes closed and arms extended straight out at the level of the shoulders for 1 minute. The examiner notes the degree of lateral rotation at the end of the maneuver.

The following examinations assess posture. For the *Romberg test*, the patient is asked to stand with feet together and arms at the side, first with eyes open and then with eyes closed (Fig. 165.7). The examiner observes the relative amount of sway, both with and without vision, and notes if the patient falls consistently to one side. In order to increase the sensitivity of vestibular defects, one can perform the *tandem Romberg test* or the *foam Romberg test* (Fig. 165.7). These tests are performed similarly to the original test. For the tandem Romberg test, though, the patient is asked to stand with one foot in front of the other heel to toe. For the foam Romberg test, the patient is asked to repeat the Romberg test while standing on large 3-inch dense foam.

Proprioception function relies on intact peripheral nerves and afferent pathways, which are evaluated in several ways. Firstly, the patient's reflexes are assessed in the standard manner. Secondly, the *proprioceptive movement test* is performed. The patient is asked to take off their shoes and socks. With the patient's eyes closed, the examiner moves the patient's toe up or down by grasping it on the sides to decrease pressure cues. The patient indicates in which direction the digit moved. Thirdly, the *vibration test* is performed. The examiner places a 128-Hz tuning fork on the malleolus of the ankle and compares the vibratory sensation to that at the wrist.

Interpretation

"Vestibular gait" does not define any specific manner and/or type of movement. Indeed, a broad array of characteristics can qualify a gait as abnormal. Furthermore, a number of causes can be the source(s) of the abnormal gait. If a patient suffers an acute unilateral loss of otolithic function, the patient will tend to veer toward the side of the lesion. Patients often rapidly compensate. Nevertheless, a variety of central brainstem and musculoskeletal lesions also produce lateral deviation during ambulation. Difficulties with gait initiation and turns as well as decreased arm swing can be seen in extrapyramidal disease. Gait ataxia implies cerebellar dysfunction and is distinctly different from the gait deviation associated with uncompensated peripheral vestibular disease. A shuffling gait should prompt the examiner to explore the possibility of Parkinson's disease and/or normal pressure hydrocephalus (NPH). Finally, exaggerated hip sway, rhythmic deviations, and an excessive reliance on touching the wall during ambulation may constitute signs of a functional gait disorder.

The stepping test was first described in 1938 by Unterberger (95) and later modified by Fukuda in 1959 (94). The ability to close one's eyes and step in place without turning depends on normal vestibulospinal and proprioceptive function. Most normal subjects deviate less than 30 degrees in rotation to one side during the step test, whereas some patients with uncompensated unilateral vestibular weakness deviate more than 30 degrees toward the weaker side. It is important to note that patients with chronic vestibular dysfunction that have compensated for their vestibular loss may perform normally on the Unterberger (Fukuda) stepping test (96).

The Romberg stance primarily tests somatosensation and proprioception functions and not the integrity of vestibular inputs (97). Patients compensating for bilateral vestibular loss are able to stand in the normal Romberg position with both eyes open and eyes closed because of adequate proprioception from a stable support surface. There are two ways, however, to increase this test's sensitivity to detect vestibular deficits: Instruct the patient to (a) stand in the tandem stance (tandem Romberg test) and then (b) step onto a piece of 3-inch dense foam (foam Romberg test). In the tandem stance, the support surface cues are sufficiently altered so that vestibular cues play a greater role in maintaining upright posture. Similarly, when the patient stands on a compliant support surface, such as 3-inch foam, somatosensory cues are muted, and vestibular cues become more important. Patients with vestibular dysfunction may demonstrate excessive hip sway (98,99).

Figure 165.7 Romberg tests. **A:** Standard Romberg test on a firm surface. **B:** Tandem Romberg test on a firm surface. **C:** Foam Romberg test on a 3" foam pad. As proprioceptive cues are altered in (**B**) and (**C**), vestibular input to balance becomes more crucial. (Adapted from Goebel JA, White JA, Heidenreich KD. Evaluation of the vestibular system, Chapter 10. In: Snow JB, Wachym PA, Ballenger JJ. (eds.). *Ballenger's otorhino-laryngology head and neck surgery.* 17th ed. Shelton, CT: People's Medical Publishing House, 2009:131–144.).

Since many of the tests assessing posture and gait rely on proprioception, it is important to evaluate the peripheral nerve status. Abnormalities in reflexes, digit proprioception, and vibration sensation should provoke the examiner to investigate causes of peripheral neuropathy (e.g., diabetes) and other neurologic processes.

Additional Tests

In addition to the basic neurotologic examination, there are several other tests that can be conducted in select patients. A number of the following tests will unmask peripheral vestibular abnormalities and can provide important diagnostic clues.

Mastoid Vibration

Vibration-induced nystagmus can be used as a diagnostic tool in patients with unilateral vestibular loss or SCC dehiscence. The examiner places a vibration source on the mastoid tip and observes the patient's eyes for nystagmus under Frenzel lenses. Nystagmus produced by mastoid oscillation in patients with vestibular asymmetry was initially described by White et al. in 2007. Mastoid vibration serves as an excitatory stimulus to both labyrinths and, in some cases of asymmetry, produces a horizontal-torsional nystagmus toward the stronger ear (100–102). In patients with superior SCC dehiscence, a vertical-torsion nystagmus in the plane of the affected SCC can be induced by mastoid vibration (100–102).

Malleolar Sign

Patients with superior SCC dehiscence may have hyperacusis to bone-conducted sounds and can present with symptoms of hearing their own pulse and/or the movements of their eyes (103,104). The bone-conducted hyperacusis can be explained by the "third mobile window" effect (19,105). To assess this unique suprathreshold bone conduction, the examiner places a 256-Hz tuning fork on the patient's malleolus. A patient with superior SCC dehiscence may hear the tone in the affected ear (106).

Sound-Evoked or Pressure-Evoked Eye Movements

Consistent eye deviations or nystagmus induced by sound or pressure changes in the middle ear is abnormal. The most common involved sites are the oval window (perilymph fistula, excessive footplate movement), round window (perilymph fistula, enlarged cochlear aqueduct), lateral SCC (perilymph fistula), and superior SCC (dehiscence).

The following maneuvers can demonstrate sound-evoked and/or pressure-evoked eye movements. With Frenzel lenses in place, the examiner observes the patient's eyes for nystagmus or tonic eye deviations concurrent with symptoms of dizziness under the following test conditions: (a) steady tragal compression or insufflations through a pneumatic otoscope used to increase (or decrease) pressure in the external auditory canal, (b) Valsalva maneuvers, and (c) presentation of loud tones via a tuning fork or an audiometer.

Hennebert sign is vertigo and/or nystagmus evoked by pressure-induced movement of the tympanic membrane and may occur in patients with perilymph fistula, otic syphilis, otic capsule erosion from disease, or SCC dehiscence. Pressure changes in the middle ear can be induced by tragal compression, pneumatic otoscopy (through a Siegel speculum), or Valsalva maneuvers. A *closed-glottis Valsalva* (bearing down) results in increased intrathoracic pressure, decreased jugular venous return, and increased intracranial pressure (Fig. 165.8). The increased intracranial pressure

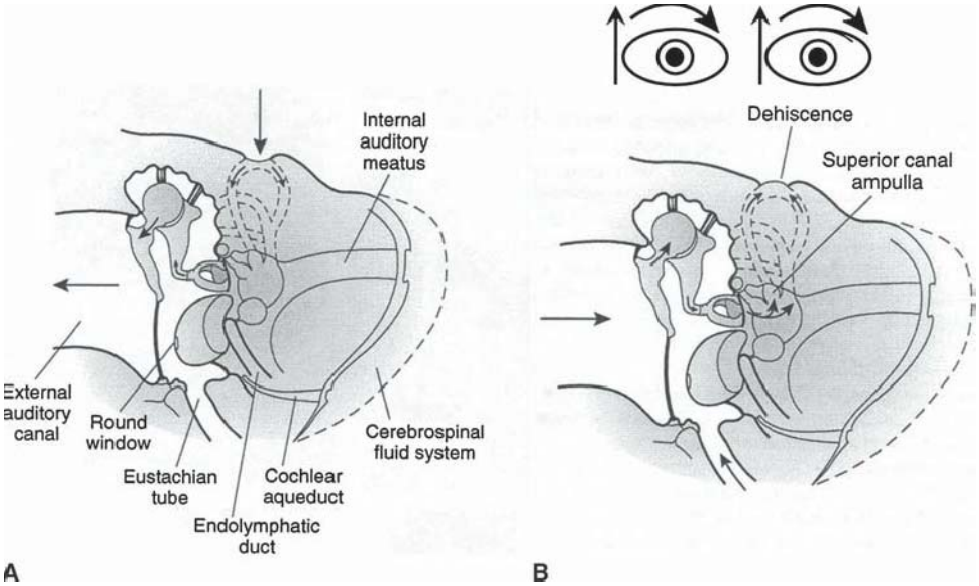

Figure 165.8 Maneuvers for diagnosing superior SCC dehiscence. Images depict the right ear. **A:** A *closed-glottis Valsalva* (bearing down) results in increased intrathoracic pressure, decreased jugular venous return, and increased intracranial pressure. The increased intracranial pressure exerts a force directly at the site of bony dehiscence. This moves the endolymph toward the superior SCC ampulla (ampullopetal), which according to Ewald's third law is inhibitory. Upon release, the endolymph flows away from the ampulla (ampullofugal), generating stimulatory nystagmus. **B:** A pneumatic otoscope or tragal compression forces air into the external auditory canal. This surge of air increases middle ear pressure, causes inward displacement of the stapes, and moves the endolymph away from the ampulla (ampullofugal), resulting in excitation. The stimulatory nystagmus is vertical–torsional with an upward slow phase that aligns with the affected SCC, and the superior pole has torsional rotation away from the affected ear. (Adapted from Hullar TE, Zee DS, Minor LB. Evaluation of the patient with dizziness, Chapter 164. In: Cummings CW, Flint PW, Harker LA. (eds.), *Otolaryngology-head and neck surgery*. 4th ed. Philadelphia, PA: Elsevier, 2004.)

exerts a force directly at the site of bony dehiscence. This moves the endolymph toward the superior SCC ampulla (ampullopetal), which according to Ewald's third law is inhibitory. Upon release, the endolymph flows away from the ampulla (ampullofugal), generating stimulatory nystagmus. An *open-glottis Valsalva* (pressure against pinched nostrils) forces air into the middle ear through the eustachian tube (Fig. 165.8). Furthermore, a pneumatic otoscope or tragal compression forces air into the external auditory canal (Fig. 165.8). These maneuvers increase middle ear pressure and cause inward displacement of the stapes. Endolymph moves away from the ampulla (ampullofugal), resulting in excitation. The stimulatory nystagmus is vertical torsional with an upward slow phase that aligns with the affected SCC, and the superior pole has torsional rotation away from the affected ear (19,107) (Fig. 165.8). Eye movements are typically conjugate. In addition, cranial–cervical junction abnormalities (Arnold-Chiari malformation in particular) produce vertical downbeat nystagmus with any maneuver that increases intracranial pressure. *Tullio phenomenon* is the occurrence of vertigo and nystagmus with exposure to sound. The examiner introduces pure tones over a range of 250 to 4,000 Hz at intensities of 100 to 110 dB. The characteristic eye findings are similar to those resulting from increased middle ear pressure (19,106).

Hyperventilation-Induced Nystagmus

Hyperventilation may induce dizziness and light-headedness in patients with psychiatric disorders (e.g., anxiety or panic disorder), but does not result in nystagmus (108,109). Hyperventilation does induce nystagmus in demyelination of the vestibular nerve (e.g., acoustic schwannoma or microvascular nerve compression) or central demyelination conditions (e.g., multiple sclerosis) (110–112). With Frenzel lenses in place, the patient is asked to hyperventilate for 90 seconds by taking deep breaths and then inhaling and exhaling in rapid succession. The examiner inspects the patient's eyes for resulting eye movements and notes the direction and character of the nystagmus. Hyperventilation-induced nystagmus is an excitatory nystagmus with the slow phase toward the healthy ear. Hyperventilation decreases both CSF and serum PCO_2 levels (113). The alkalotic environment causes albumin to bind to calcium. The reduction in extracellular calcium levels leads to improved axonal conduction in partially demyelinated nerve fibers (114–116). Interestingly, it has been reported that after surgical resection of acoustic schwannomas, hyperventilation no longer induces nystagmus, presumably because the demyelinated nerve fibers have been removed (112).

CONCLUSION

The diagnosis and management of the patient with dizziness and imbalance can be perplexing and challenging. Therefore, it is vital that practitioners recognize the complexity of the problem and develop a systematic and efficient approach. Taking a careful history and deciphering a true understanding of the patient's symptoms are crucial in developing a differential diagnosis. Furthermore, it is important to perform a systematic and structured neurotologic examination. Between a detailed history and a structured neurotologic examination, the physician will be best equipped to provide an accurate diagnosis and a rational treatment approach that addresses all major contributing factors.

HIGHLIGHTS

- The three primary sensory inputs responsible for balance originate from the vestibular, visual, and somatosensory (proprioceptive) pathways.
- A structured and thorough discovery of all pertinent historical events is critical in the evaluation of the dizzy patient.
- The head impulse test (HIT) is a bedside technique used to detect unilateral or bilateral vestibular hypofunction.
- Postheadshake nystagmus is considered a pathologic sign of vestibular input asymmetry in the plane of rotation.
- The dynamic visual acuity test (DVAT) has been developed and studied for the purpose of determining gaze stability during head movements at higher frequency (greater than 2 Hz) and peak velocity (greater than 120 degrees/s).
- Benign paroxysmal positional vertigo (BPPV) is characterized by a sudden onset of episodic vertigo lasting from a few seconds to several minutes that is induced by head movement in certain positions and is the most common cause of peripheral positioning nystagmus.
- It is critical to understand Ewald's laws in order to accurately interpret nystagmus resulting from peripheral vestibular pathology.

Peripheral Vestibular Disorders

166

Yuri Agrawal *Lloyd B. Minor* *John P. Carey*

GENERAL PRINCIPLES

The vestibular end organ consists of five organs: three semicircular canals (anterior, posterior, and horizontal), and two otolith end organs—the saccule and the utricle. The semicircular canals detect angular head rotation, while the otolith end organs detect translational head motion and the head's orientation with respect to gravity. Hair cells in the right and left vestibular organs fire at a tonic baseline rate; if the head is turned toward the right, the hair cells of the right horizontal canal increase their firing rate while the hair cells of the left horizontal canal decrease their firing rate. The opposite changes occur with head turns to the left. Sensory input from the vestibular periphery is relayed centrally via the vestibular nerves; the superior vestibular nerve carries information from the horizontal and superior semicircular canals and the utricle while the inferior vestibular nerve transmits input from the posterior semicircular canal and saccule. The brain compares the inputs from right and left vestibular organs in order to determine that a change in head position has occurred and generates compensatory eye movements and postural changes. Collectively, the vestibular apparatus encodes information about head position and contributes to the maintenance of gaze and postural stability (via the vestibuloocular reflex (VOR) and vestibulospinal reflex respectively) (1).

In this chapter, we review peripheral vestibular disorders, which are characterized by pathology located in the peripheral vestibular end organs. The hallmark symptom of peripheral vestibular dysfunction is vertigo, which occurs if the right- and left-sided vestibular nerves fire asymmetrically *in the absence of a head movement*, creating an illusory sense of motion. We categorize peripheral vestibular disorders based on the clinical manifestations of vertigo (Table 166.1). Vertigo can be episodic, resulting from a reversible unilateral loss or gain of vestibular function, either of which can produce an asymmetry in the firing rates of the right- and left-sided vestibular nerves. Peripheral vestibular diseases characterized by episodic disruption of vestibular function include Ménière's disease, where loss of vestibular function occurs for minutes to hours, as well as vestibular neuritis, labyrinthitis, and immune-mediated inner ear disease (IMIED), where loss of function can occur for over 24 hours. In migrainous vertigo, disruption of vestibular function may last for variable periods of time, in some events for minutes to hours, but in others for days. Peripheral vestibular disorders resulting from intermittent excitation in vestibular function include benign paroxysmal positional vertigo (BPPV) and superior canal dehiscence (SCD) syndrome. Perilymph fistulas may produce either an episodic disruption or excitation of vestibular function. A third category of peripheral vestibular disorders are those that result from chronically inadequate vestibular function. Chronic unilateral loss of vestibular function can be due to incomplete recovery after vestibular neuritis or labyrinthitis, long-term sequelae of Ménière's disease, damage from cholesteatoma or chronic otitis media, etc. Some specific other causes are discussed in other chapters, including temporal bone trauma (Chapter 150) or acoustic neuroma (Chapter 159). Chronic bilateral vestibular dysfunction typically occurs in the setting of a systemic exposure, such as to aminoglycoside antibiotics or chemotherapeutic agents, or may be genetic in origin.

BRIEF EPISODIC DISRUPTION OF UNILATERAL VESTIBULAR FUNCTION

Ménière's Disease

Ménière's syndrome is an inner ear disorder characterized by spontaneous attacks of vertigo, fluctuating low-frequency sensorineural hearing loss, aural fullness, and tinnitus. When the syndrome is idiopathic and cannot be attributed to any other cause (e.g., syphilis, IMIED, surgical trauma),

TABLE 166.1 BASIC PRESENTATIONS OF PERIPHERAL VESTIBULAR DYSFUNCTION

1. Episodic disruption of unilateral vestibular function
   Lasting minutes-hours
   - Ménière's disease
   - Perilymph fistula

   Lasting >24 h
   - Vestibular neuritis
   - Labyrinthitis
   - IMIED

   Lasting variable periods of time
   - Migrainous vertigo
2. Brief/episodic excitation of unilateral vestibular function
   - BPPV
   - SCD syndrome
   - Perilymph fistula
3. Chronically inadequate vestibular function
   Unilateral
   - Unilateral vestibular hypofunction following vestibular neuritis, trauma, etc.
   - Acoustic neuroma

   Bilateral
   - Aminoglycoside toxicity
   - Chemotherapy
   - Familial

it is referred to as Ménière's disease (2). Ménière's syndrome exhibits a relapsing–remitting pattern, with episodic attacks terminated by periods of restitution to normal auditory and vestibular function. Additionally, auditory and vestibular function may decline over time (3).

Clinical Features

The prevalence of Ménière's disease has been reported to range from 34.5 per 100,000 persons in Japan (4), 157 per 100,000 persons in the United Kingdom (5), 190 per 100,000 in the United States (6), to 513 per 100,000 in Finland (7). Disease onset typically occurs in the fourth to sixth decade of life, with a 1.3–1.9:1 female predominance (4,6). The extent to which Ménière's disease occurs bilaterally has been a subject of considerable controversy. House et al. (8) found a 24% overall prevalence of bilateral Ménière's disease, with 11% being bilateral at initial presentation, and a 14% rate of progression from unilateral to bilateral disease. The diagnosis of Ménière's disease is largely clinical at this time; there are no pathognomonic tests that confirm this diagnosis. The most widely-used guidelines to establish a diagnosis of Ménière's disease were published by the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS), which termed "definite" Ménière's disease as two or more spontaneous episodes of vertigo, each lasting 20 minutes or longer; hearing loss documented by audiograms on at least one occasion; tinnitus or aural fullness in the affected ear; and other causes excluded (typically with gadolinium-enhanced magnetic resonance imaging [MRI] of the cranial base) (9). The staging system established by the AAO-HNS is based on audiometric criteria, with 4-frequency pure-tone averages at 0.5, 1, 2, and 3 kHz of less than 25, 26 to 40, 41 to 70 and greater than 70 corresponding to Stages 1, 2, 3, and 4 respectively.

The presentation of Ménière's disease typically includes recurring attacks of vertigo (96.2%), with tinnitus (91.1%) and ipsilateral hearing loss (87.7%) (10). The clinical course of Ménière's disease varies considerably between patients, from long periods of remission punctuated by episodic attacks to intervals of unrelenting attacks. Longitudinal studies suggest that vertigo ceases spontaneously in 57% of cases at 2 years and 71% after 8.3 years (11). Patients classically present with a low-frequency sensorineural hearing loss that is fluctuating and progressive. With long-standing disease (greater than 10 years), the audiometric pattern flattens and the hearing loss typically stabilizes at a pure-tone average of 50 dB and a speech discrimination score of 50% (12). Profound sensorineural hearing loss occurs in 1% to 2% of patients (13); if the losses are bilateral, patients may benefit from cochlear implantation (14).

Endolymphatic Hydrops

Endolymphatic hydrops has long been held to be the pathologic basis for Ménière's disease (15–17). Endolymph, the potassium-enriched fluid in the inner ear, may be either excessively synthesized or inadequately resorbed, resulting in expansion of the endolymphatic space (17,18). Endolymphatic hydrops typically involves the pars inferior of the labyrinth (composed of the saccule and cochlea) (16,19). The pars superior (utricle and semicircular canals) may also be involved in endolymphatic hydrops, although changes tend to be less dramatic and occur less frequently.

Several mechanisms have been suggested to explain how endolymphatic hydrops may produce the spontaneous attacks of vertigo characteristic of Ménière's disease. The most prominent theory holds that hydropic distension of the endolymphatic duct causes rupture of the distended membranes, a phenomenon that has been observed throughout the labyrinth (20). Membrane rupture allows the potassium-rich endolymph to leak into the perilymphatic space and contact the basal surfaces of the hair cells as well as the eighth cranial nerve. Initial excitation and then subsequent inhibition of the hair cells manifests as a direction-changing nystagmus and may underlie episodic vertigo. Long-term declines in auditory and vestibular function may be the result of repeated exposure of the vestibular hair cells to toxic levels of potassium-enriched perilymph (21). Recent studies have challenged the primacy of endolymphatic hydrops in the pathophysiology of Ménière's disease, and have suggested that endolymphatic hydrops may be a marker of disordered cochlear homeostasis but not necessarily directly responsible for the symptoms of Ménière's disease (22).

Physiologic Tests in Ménière's Disease

The use of electrocochleography is based on endolymphatic hydrops as a presumed pathologic correlate of Ménière's disease. Electrical potentials generated by the cochlea are measured in response to repeated sound stimulation with clicks or tonebursts. The cochlear field potential responses include the cochlear microphonic potential and the summating potential (SP), both of which represent cochlear hair cell function, and the compound action potential (AP), which reflects auditory nerve activity and corresponds to wave I of the auditory brainstem reflex. The SP has been observed to be larger in response to clicks or more negative in response to tonebursts in patients with Ménière's disease. Using clicks, for example, a typical upper limit of normal for the SP/AP ratio is 0.4 (23). SP changes in Ménière's disease are thought to reflect hydropic distension of the basilar membrane into the scala tympani causing an increase in the normal asymmetry of its vibration. The sensitivity of the SP/AP ratio has been reported to be 50% to 70% (24), and efforts to augment the sensitivity have included combining the SP/AP ratio with SP amplitude, AP latency, and audiometric parameters (25). Yet while studies find that electrocochleographic findings with audiometric considerations can segregate cases of definite Ménière's disease from normals, the ability of electrocochleography to discriminate between cases of possible or probable Ménière's disease and normals is less clear (25). It is in these less-clear cases that additional information would be most helpful.

Caloric and head impulse testing are both tests of semicircular canal function. In caloric testing, bithermal irrigation is applied to the external auditory canals, which causes a convective movement of endolymph within the ipsilateral horizontal semicircular canal (26). The movement of fluid within the horizontal canal results in excitatory or inhibitory deflection of the cupula (depending upon the direction of endolymph flow). Motion of the cupula then leads to hair cell excitation or inhibition with a corresponding change in the discharge rate of vestibular-nerve afferents. Compensatory eye movements are thereby elicited (corresponding to the slow phases of nystagmus), followed by fast resetting eye movements (corresponding to the fast phase of nystagmus). The maximum velocities of the slow phases of nystagmus are compared bilaterally and used to compute unilateral weakness or caloric asymmetry. Depending on the normative data developed by individual vestibular laboratories, a caloric asymmetry of 20% or greater is usually considered indicative of unilateral peripheral vestibular hypofunction.

Head impulse (or head thrust) testing assesses the integrity of the angular vestibuloocular reflex (AVOR). Head and eye movements are recorded during high-velocity, high-acceleration rotary head impulses in the excitatory direction for each of the six semicircular canals. Normal subjects are able to maintain visual fixation on a target during rapid head movement and thus have gain values (computed as the ratio of eye velocity to head velocity) close to 1.0 (27).

A significant reduction in the caloric response of affected ears has been observed in 42% to 79% of individuals with unilateral Ménière's disease (28–34). In contrast, abnormalities of the AVOR in Ménière's disease are much less prevalent, although there appears to be a correlation between head impulse test gain asymmetry and caloric unilateral weakness percentage (29). Although caloric and head impulse testing are both measures of semicircular canal function, they may be capturing distinct phenomena. Caloric irrigation causes a slow convective flow of endolymph and provides a low frequency stimulus to the vestibular system. In contrast, high-velocity rotary head thrusts cause rapid endolymph movement and generate a high frequency input to vestibular afferents. It is possible that Ménière's disease preferentially impairs the ability of the vestibular apparatus to process low-frequency signals. It should be noted that the low-frequency caloric stimulus is a nonphysiologic input, whereas the high-frequency head thrust approximates commonly occurring stimulus frequencies to the vestibular apparatus during walking and running. Thus it is also possible that mechanisms of central adaptation can only be established for physiologic stimuli (leading to normal responses to head impulse testing) but not for inputs outside the normal range (i.e., caloric stimuli).

Vestibular-evoked myogenic potentials (VEMPs) are thought to reflect otolith function. The cervical VEMP (cVEMP) in response to air-conducted clicks or tonebursts appears to be generated by a sacculocollic reflex. In the afferent limb of this reflex pathway, acoustically-sensitive cells in the saccule respond to brief, loud, monaural sound stimuli and transmit an electrical signal centrally via the inferior vestibular nerve. The efferent limb of this reflex arc sends an inhibitory impulse to the fibers of the ipsilateral sternocleidomastoid muscle; electromyographic recordings from this muscle in response to a sound input thus reflect saccular function (35,36).

cVEMP responses to click stimuli were observed to be delayed or absent in 51% to 54% of patients with Ménière's disease (37,38) compared to the normal click-evoked response rates of 98%. Normal individuals demonstrate greatest sensitivity of their sacculocollic reflex over the 200 to 1,000 Hz frequency range (39,40); patients with Ménière's disease are noted to exhibit altered frequency tuning, such that the greatest sensitivity of the sacculocollic reflex appears to occur at higher frequencies and across a broader frequency range compared to normal subjects (41). Frequency tuning may be a function of the resonance properties of the saccule (which in part reflects the size of the saccule). Moreover, individuals with severe saccular dysfunction who experience drop attacks—otherwise known as otolithic crises of Tumarkin (42,43)—have the greatest blunting and frequency shift of their cVEMP tuning curves (44). Additionally, 27% of individuals with unilateral Ménière's disease were found to have cVEMP response abnormalities in their unaffected ear; the cVEMP tuning curves in these asymptomatic ears were noted to be

intermediate in phenotype between affected and normal ears (45). cVEMP testing shows particular promise as a measure of Ménière's disease severity and in its ability to prognosticate bilateral disease.

Treatment

Given that the pathologic basis of Ménière's disease remains elusive, it follows that a curative treatment remains to be elucidated. Current therapies are directed at mitigating symptoms, particularly vertigo. First-line medical regimens include salt restriction and diuretics, aimed at alleviating endolymphatic hydrops. Betahistine, an H1-histamine receptor antagonist that increases inner ear blood flow, has been shown to reduce the frequency and severity of vertigo episodes. Betahistine is widely used in Europe in the treatment of Ménière's disease although its use is limited in the United States given insufficient evidence for its efficacy (46). Increasing evidence supports the use of corticosteroids, particularly delivered intratympanically, in the treatment of Ménière's disease. One large retrospective study found that control of vertigo symptoms was achieved in 91% of patients treated with intratympanic dexamethasone, allowing them to defer or avoid ablative therapies (47).

Medical therapy is insufficient to control vertigo symptoms in 10% of cases (48). Options for patients with refractory Ménière's disease include surgical decompression of the endolymphatic system, and surgical or chemical ablation of vestibular function. In endolymphatic sac surgery, a transmastoid approach is used to decompress the sac with or without placement of a shunt to drain endolymph. Studies demonstrate positive outcomes from endolymphatic shunt surgery in terms of hearing preservation and vertigo control (49), although a recent meta-analysis found that there is insufficient evidence showing efficacy of this procedure relative to placebo (50). Selective vestibular neurectomy via middle fossa or posterior fossa approach has been shown to relieve vertigo symptoms in over 90% of cases, although potential complications of these procedures, including hearing loss, facial nerve weakness, cerebrospinal fluid (CSF) leak, speech and language deficits (from temporal lobe retraction in the middle fossa approach), and headaches (from the posterior fossa approach) must be considered. Surgical labyrinthectomy achieves excellent vertigo control rates, although hearing in the operated ear is abolished.

Surgical procedures are increasingly being supplanted by chemical ablation of the peripheral vestibular apparatus using intratympanic gentamicin. Gentamicin is a relatively selective vestibulotoxic aminoglycoside antibiotic that is preferentially taken up by type I hair cells of the vestibular neuroepithelium (51). The use of low-dose intratympanic gentamicin has been shown to yield 70% to 90% vertigo control rates (52), and is associated with hearing loss in only 17% of cases (53). We have demonstrated that AVOR gains in Ménière's disease are typically normal before intratympanic gentamicin administration, and that they drop significantly after gentamicin, but not as much as after surgical labyrinthectomy (54). Studies in the chinchilla suggest that the lesion caused by intratympanic gentamicin primarily affects type I vestibular hair cells and may damage stereocilia on type II hair cells; however, vestibular nerve afferents continue to fire spontaneously after intratympanic gentamicin treatment (51,55). These findings suggest that a benefit of intratympanic gentamicin treatment over surgical ablation is that the gentamicin lesion is partial and does not create the kind of large static imbalance in vestibular nerve firing that accompanies surgical ablation. Therefore, adaptation to the intratympanic gentamicin lesion may be less challenging than to surgical ablation.

Migrainous Vertigo

Clinical Features

Vertigo is a common symptom of migraines, occurring in 25% of migraine patients (56). Vertigo may occur as an aura, which is a focal neurologic symptom preceding the headache. More commonly, however, attacks of vertigo occur independently and in some cases in place of the headache (57). In fact, typical migraine headaches occur with the vertigo spells in only about half of cases (58,59). Patients often report a prior history of migraine headaches that seem to have resolved. Milder head or neck pain or pressure may replace the pounding headaches and accompany the dizziness symptoms. The dizziness can be described as vertigo (spinning, rocking, swaying) or simply disequilibrium. The symptoms may be quite variable in duration, lasting minutes to days in episodic cases, or may present as constant disequilibrium lasting months. In approximately half of episodic cases the spells of vertigo or disequilibrium last more than a day (60), a feature that often helps distinguish migrainous vertigo from Ménière's disease. Photophobia, menstrual association, and nasal stuffiness at the time of attack all increase the odds that vertigo is migrainous in origin, especially if there is no history of hearing fluctuation or positional component (61). A family history of migraines may be helpful in the diagnosis, as may a history of unexplained falling spells or motion sensitivity as a child (62). Interestingly, the prevalence of migraine in patients with Ménière's disease is significantly higher than in the general population (63,64), and there may be a pathophysiologic link between the two disorders. This makes it sometimes difficult to distinguish the two in a given patient, and both may need to be treated for successful control of vertigo in some individuals.

Pathophysiology

Two pathophysiologic mechanisms have been hypothesized to cause migraine-associated vertigo: central electrical disturbances and peripheral trigeminovascular dysfunction. Functional MRI studies have demonstrated the centrifugal spread of depressed metabolic activity originating from the occipital cortex during visual aura progression (65).

This cortical spreading depression appears to represent a propagating wave of disturbed membrane ionic homeostasis; indeed, studies have linked at least one form of migraine (familial hemiplegic migraine) to several possible mutations, for example, in a calcium ion channel gene on chromosome 19 (66). Baloh (67) has suggested that the features of more common migraine syndromes resemble those of many inherited ion channelopathies. This may account for the efficacy of agents that cause an ion channel blockade, such as calcium channel blockers or beta-blockers, in the prevention and treatment of migraine. The spreading depression triggered by ion channel defects appears to affect not only cortical structures but also more caudal regions in the brainstem (68). A variety of structures may be affected by aberrant electrical activity in the tightly-packed brainstem anatomy. Involvement of the medial lemniscus, through which touch and proprioceptive fibers ascend to the thalamus, may contribute to the pain and allodynia (hypersensitivity to touch) experienced by migraineurs. Involvement of the ascending fibers of the reticular activating system, which regulate alertness, may explain the fatigue that often occurs during and after a migraine episode. Spread of the metabolic depression to the descending fibers of the brainstem that are responsible for the common integrator function of the vestibular and oculomotor systems may lead to disturbances of the VOR. The electrical disturbance may also affect the cochlear and vestibular nuclear complexes, producing the symptoms of hearing loss and vertigo. Indeed, transient sensorineural hearing loss as well as reduction in vestibular responses have been documented in patients with migraine (57,69,70).

Another possible mechanism to explain the observed labyrinthine dysfunction is activity in the trigeminovascular efferent system. Dysfunction of the trigeminal brainstem nuclei (possibly owing to spreading depression) may lead to aberrant efferent signals in the trigeminal nerve. The trigeminal nerve arborizes extensively in the head and neck, with efferents also demonstrated in the inner ear (71). Release of vasoactive compounds such as calcitonin gene-related peptide and Substance P by the trigeminal nerve may cause plasma extravasation and produce a local aseptic inflammation (72). Plasma extravasation from the spiral modiolar artery has been demonstrated after stimulation of the trigeminal ganglion, so it seems possible that a migrainous mechanism could directly affect cochlear and peripheral vestibular function (73). If so, this might explain the difficulty in separating some cases of migrainous vertigo from apparent Ménière's disease, as the peripheral effects of such trigeminovascular disturbances might mimic what we now think of as Ménière's disease.

Treatment

The treatment of migrainous vertigo can be quite successful if approached in a stepwise fashion, beginning with dietary and lifestyle modifications, and proceeding if needed to recognized migraine prophylactic agents (60). Lifestyle changes should include regular sleep and exercise, and the identification and avoidance of migraine triggers. Stress, hormonal changes, weather and barometric pressure changes often incite migraine attacks. Common food triggers include byproducts of food aging and fermentation, such as red wine, aged cheese, yeast bread and yogurt, which contain high levels of tyramine. Foods that contain amines similar to our own neurotransmitters, such as caffeine, nitrates and other preservatives, chocolate, and various forms of glutamate including monosodium glutamate, have also been found to be migraine triggers and should be avoided. For symptoms that are constant and for which triggers cannot be identified or eliminated, the use of medications that raise the threshold above which migraines are triggered should be considered. Such prophylactic medications include calcium channel blockers, beta blockers, antidepressants such as nortriptyline or venlafaxine, and anticonvulsants including sodium valproate, gabapentin, and topiramate. Prophylactic medications should be selected based on the tolerability of their side effects in a given patient. Typically, benefits are seen after 6 to 8 weeks of therapy, and a realistic goal is to reduce symptom frequency and severity by 50% to 70%. For migraine attacks that persist despite lifestyle and dietary modifications and the use of prophylactic medications, migraine abortive medications such as the triptans can be considered. Abortive medications should not be used more than six to eight times per month, given their known rebound effects. Vestibular rehabilitation therapy has also been shown to significantly improve functional status in patients with migraine-associated vertigo (74,75).

Perilymph Fistula

Fractures of the bone of the labyrinthine capsule separating the inner ear from the middle ear and mastoid or disruption of the bone or membranes in the area of the oval or round windows can lead to a perilymph fistula with consequent sensorineural hearing loss and episodic vertigo (76,77). This diagnosis can be made with certainty following stapedectomy in which the prosthesis becomes dislodged and perilymph leaks from the open fenestra into the middle ear, and with a traumatic temporal bone fracture that allows a leakage of perilymph. In these situations, patching of the fenestration or of the area of the fracture can lead to stabilization of hearing and to eradication of vertigo. Additionally, labyrinthine fistulae, with or without leakage of perilymph, can occur in the setting of chronic otitis media, typically with cholesteatoma (78).

More ambiguous situations are encountered when a perilymph fistula is suspected in the absence of the pathologic entities described above. Potential anatomic communications between the middle and inner ears may account for the development of spontaneous perilymph fistulas (79), although these microfissures may be common in the temporal bone and not necessarily pathologic (80).

Goodhill (81) proposed that an implosive or explosive force can lead to membranous ruptures and to formation of perilymph fistula. A clear association has been reported between the Mondini deformity (partially formed cochlea lacking the normal 2½ turns) and perilymph fistula (82).

Criteria for determining when exploration for a perilymph fistula might be indicated have been difficult to establish because of the absence of an agreed upon diagnostic test that would be sensitive and specific for the identification of perilymph fistula. Studies that use electrocochleography have indicated that an abnormal ratio of SP to AP is seen in many patients with an acute leakage of perilymph (83). Fistula tests that involve positive and negative pressure in the external auditory canal and inspection for evoked eye movements (Hennebert sign) or symptoms have also been used. This testing method has been combined with platform posturography to look for increased sway in association with the pressure stimuli (84,85).

Findings at the time of middle ear exploration in patients with sudden deafness, vestibular symptoms, and/or auditory symptoms thought perhaps to be related to perilymph fistula have differed between studies and have been at times equivocal (86–88). Some patients with negative explorations have been reported to improve after surgery. The absence of an observed leakage of perilymph at the time of surgical exploration has been interpreted in different ways: that a fistula does not exist, that the fistula may be intermittent and not present at the time of surgical exploration, or that the fistula may not be detectable with conventional operative microscopy. Recommendations about how to proceed in cases in which a fistula was not identified (whether or not to patch the round and oval windows with fascia) have varied. In reports of endoscopic exploration of the middle ear when there were symptoms that could be due to spontaneous perilymph fistula, Poe and Bottrill (89) did not find evidence of a leak in any case.

The dilemmas surrounding the diagnosis and treatment of spontaneous perilymph fistula are likely to persist until a diagnostic test with high sensitivity and specificity is developed and until verification of a perilymph fistula can be definitively established at the time of surgery. Assays for beta-2 transferrin and beta-trace protein (proteins thought to be unique to perilymph and CSF) in tympanic cavity aspirates have been investigated, though the sensitivity of these analyses is low (90,91). Thus the questions posed in a comprehensive review of perilymph fistulas persist: "Can perilymph fistulas occur 'spontaneously'? What symptoms are specifically associated with such fistulas? What tests can diagnose a fistula? What is the 'gold standard' for confirming the presence of a fistula? How should a fistula be treated?" (77).

Vestibular Neuritis

Vestibular neuritis is a syndrome of sudden onset vertigo lasting for days without associated hearing loss or neurologic impairment (92). If hearing loss also occurs, this is referred to as labyrinthitis. Vestibular neuritis is thought to result from the reactivation of a latent herpes simplex virus type 1 infection in the vestibular ganglia. Histopathologic studies have demonstrated degeneration in Scarpa ganglion and the vestibular nerve after attacks of vestibular neuritis (93,94). Typically the superior division of the vestibular nerve is affected, possibly due to anatomic differences in the bony canals between the superior and inferior divisions (95,96). A reduction or loss of caloric responsiveness is the most consistent laboratory finding (97). Three-dimensional eye movement studies implicate only the horizontal and superior canals in generating the acute spontaneous nystagmus, whereas the posterior canal is still functional in many cases (98,99). The saccule continues to function in about two-thirds of patients as measured by cVEMP. About one-third of these individuals can go on to develop posterior canal BPPV, perhaps due to otolithic debris released from the damaged utricle (100).

A prospective, randomized, double-blind trial of 141 subjects with acute vestibular neuritis evaluated the relative efficacy of methylprednisolone alone, valacyclovir alone, and both methylprednisolone and valacyclovir compared to placebo in the treatment of vestibular neuritis as measured by caloric responsiveness within 3 days of the onset of symptoms and 12 months afterward (101). The study found a significant effect of methylprednisolone but not of valacyclovir on the recovery of a caloric response. The combination of methylprednisolone and valacyclovir was not superior to corticosteroid monotherapy. Steroids are thus the mainstay of treatment. Vestibular suppressants can relieve acute symptoms, but long-term use can impair compensation and should be minimized. Vestibular physical therapy should be initiated as early as possible to promote central compensation for any peripheral loss of function.

Immune-Mediated Inner Ear Disease

IMIED represents a syndrome of inner ear inflammation resulting from autoimmune mechanisms. Considerable evidence suggests that the inner ear is capable of mounting both humoral and cell-mediated immune responses (102–106). The endolymphatic sac appears to play a pivotal role in inner ear immunity; immune responses to antigenic stimulation in the cochlea were found to be significantly less robust in animals that had undergone sac obliteration (107). Temporal bone studies have demonstrated four histopathologic patterns associated with IMIED: (a) endolymphatic hydrops (or fluid-filled distension of the scala media as also seen with Ménière's disease); (b) acute labyrinthitis resulting in atrophy of hair cells and their supporting structures; (c) proliferation of fibrous tissue or bone ("neo-osteogenesis") and (d) neuronal atrophy.

IMIED may be a primary inner ear process with no evidence of associated systemic immune disease. In 15% to 30% of cases, IMIED is associated with systemic autoimmune conditions (108). It is a common feature of

Cogan syndrome, polyarteritis nodosa and relapsing polychondritis, and occurs more rarely with Wegener granulomatosis, systemic lupus erythematosus, sarcoidosis, Behçet disease and Sjögren syndrome (109). Given its association with various vasculitides, the presumed pathophysiologic mechanism for IMIED is vasculopathic changes to the labyrinthine arteries that supply the inner ear.

Clinical Features

IMIED typically presents with episodic auditory and vestibular symptoms. The onset of hearing loss in IMIED is relatively rapid, occurring over a course of weeks to months, distinguishing it from sudden sensorineural hearing loss that occurs over hours to days, and from slowly progressive hearing loss (e.g., presbycusis), which takes months to years to evolve. One ear may be affected first, followed almost invariably by decreased hearing in the contralateral ear within weeks to months. Progression to profound bilateral sensorineural hearing loss may occur in some cases. Vestibular symptoms in IMIED may also fluctuate over time, often in concert with fluctuations in hearing. Vertigo accompanies hearing loss in IMIED in over 50% of cases, while 25% to 50% of patients experience tinnitus and aural fullness associated with their hearing loss (108).

The co-occurrence of hearing loss exacerbations, vertigo, tinnitus, and aural fullness can also suggest a diagnosis of Ménière's disease. The principal method for distinguishing between these two clinical entities is by considering the time course of symptoms. In Ménière's disease, hearing loss occurs over a period of years rather than the weeks to months characteristic of IMIED. Additionally, Ménière's disease is more likely to be unilateral, with progression to the contralateral ear occurring in fewer than 50% of cases (110). It is critical to distinguish between IMIED and Ménière's disease given that IMIED is more likely to respond to the early initiation of aggressive immunosuppressive therapy. The time course of audiovestibular symptoms in IMIED can also be similar to neurosyphilis involving the inner ear (see Chapter 156 for further details); serologic testing for treponemal antibodies is critical to distinguish between these clinical entities.

A history of ocular disease in a patient with IMIED is a characteristic feature of Behçet disease, Cogan syndrome, relapsing polychondritis, and sarcoidosis. Ocular inflammation, however, may not coincide temporally with audiovestibular symptoms. Ocular inflammatory disease can take the form of conjunctivitis, keratitis (corneal inflammation), scleritis (inflammation of the white outer fibrous layer), uveitis (inflammation of the uveal layer—the iris, choroid and ciliary body), or retinal vasculitis. Ocular symptoms for any of these diseases can include redness of the eye, blurry vision, photophobia, floating spots, or eye pain. Associated clinical symptoms help to distinguish between disease entities. Behçet disease is typically accompanied by oral and genital ulcers. Cogan syndrome is defined as a triad including audiovestibular dysfunction, interstitial keratitis (similar to that seen with syphilis) and other forms of ocular inflammation, and systemic autoimmune vasculitis. A hallmark symptom of relapsing polychondritis is inflammation of the auricular cartilages, which manifests as ear erythema, edema, and tenderness that spares the ear lobule and external auditory canal. Sarcoidosis is an idiopathic granulomatous disease associated with hilar lymphadenopathy, arthralgias, and erythema nodosum. Neurosarcoidosis refers to granulomatous involvement of the central nervous system (CNS); typical features include facial paralysis, visual changes, and hearing loss (associated with cranial neuropathies). Definitive diagnosis of neurosarcoidosis is made based on biopsy; however, given the difficulty of obtaining CNS tissue ancillary studies such as elevated serum angiotensin-converting enzyme levels or calcium levels may suggest the diagnosis. A clinical history suggestive of IMIED should prompt questioning about associated ocular symptoms.

There is no pathognomonic serologic test for IMIED; the data are perhaps most compelling for the antibody to the 68 kDa protein. In a cohort of 72 patients with idiopathic, progressive, bilateral sensorineural hearing loss, Moscicki et al. (111) found significantly higher levels of an antibody to a 68 kDa inner ear protein in patients whose hearing loss responded to corticosteroid treatment. This inner ear protein was initially thought to be heat shock protein-70, a biologically plausible hypothesis given the known role of heat shock proteins in the immune response (112,113). However, this hypothesis was not borne out in subsequent experimental analyses (114,115). More recent work has suggested that the antibody to the 68 kDa antigen is the Kresge Hearing Research Institute-3 antibody, which binds to an antigen on the supporting cells of the Organ of Corti and results in outer hair cell depletion and hearing loss (116,117). Additionally, the 68 kDa antigen itself has been identified as likely being the choline transporter-like-2 (CTL-2) protein (118). CTL-2 regulates the function of choline, which is a constituent of the neurotransmitter acetylcholine as well as of the cell membrane component phosphatidylcholine and may be required for hair cell survival. Knowing if a patient is seropositive for the antibody to the 68 kDa antigen is of potential clinical value given studies showing the increased effectiveness of steroids in these patients (119), although commercial assays for the antibody to the 68kDa protein are not widely available or well validated (120). In patients with suspected IMIED based on clinical presentation, obtaining an erythrocyte sedimentation rate or C-reactive protein may also be helpful to screen for a systemic autoimmune disease (121). Other serologic tests for IMIED have included the lymphocyte transformation test, which targets type II collagen, and the lymphocyte migration inhibition test, although the sensitivity and specificity of these tests are low and they are no longer in common clinical use. Diagnosing IMIED remains primarily based on clinical history, responsiveness to steroid therapy, and evidence of associated systemic autoimmune disease.

Treatment

IMIED is a particularly important diagnosis to make because it is one of the few causes of bilateral hearing loss or vestibulopathy that is potentially reversible. As such, IMIED is worth treating aggressively. The mainstay of treatment consists of corticosteroids; studies have shown that 60% to 70% of patients diagnosed with IMIED demonstrate clinical improvement following steroid therapy (122,123). If the patient does not respond to 2 weeks of steroids, cyclophosphamide or methotrexate may be added to the regimen. If patients show no sign of a clinical response to combined prednisone and adjunctive therapy after 3 months, therapy is discontinued to prevent treatment complications. Studies have also evaluated intratympanic application of steroids, with mixed results (124,125). The efficacy of corticosteroids in the treatment of IMIED may be derived from their glucocorticoid (anti-inflammatory) as well as mineralocorticoid effects (126). Patients who are refractory to medical therapy or who cannot be maintained on corticosteroids due to complications may benefit from hearing aids and possibly be candidates for cochlear implantation.

BRIEF EPISODIC EXCITATION OF UNILATERAL VESTIBULAR FUNCTION

Benign Paroxysmal Positional Vertigo

BPPV is the most common cause of dizziness, accounting for around 40% of vertigo complaints from patients (127). BPPV may be caused by cupulolithiasis, whereby otoconial debris are lodged in the cupula of the semicircular canals, or canalolithiasis, whereby debris are free-floating in the semicircular canal endolymphatic fluid. Typical symptoms are brief episodes of vertigo lasting less than a minute that occur after turning the head; a classic presentation is brief vertigo when rolling over in bed. The ectopic otoconia are thought to arise from the utricle, possibly following a head trauma or an ischemic injury to the inner ear. The posterior canal is usually the affected canal. Horizontal canal BPPV does occur, typically resulting from a repositioning maneuver whereby free-floating otoconia have not yet migrated back into the utricle as intended. Superior canal BPPV occurs, but even more rarely.

The diagnosis of BPPV is typically made by observing nystagmus patterns following the Dix-Hallpike positioning maneuver, whereby patients start sitting and are lowered to a supine position with the head extended and turned 45 degrees to the right or left side (Fig. 166.1) (92). The right Dix-Hallpike maneuver brings the right posterior canal into an earth-vertical plane and will cause any loose otoconia to move in an ampullofugal, or excitatory, direction. Interpreting the nystagmus of BPPV is critical to identifying the affected canal. For the posterior canal, which is normally excited by rotating the head up and rolling it toward the ipsilateral side, the appropriate nystagmus is compensatory to this perceived head movement: It has a slow phase that is downward and rolling toward the contralateral side. The fast phases of the nystagmus will beat upward and roll toward the ipsilateral side, which, being toward the ground in the Dix-Hallpike position, led to the term, "geotropic." A

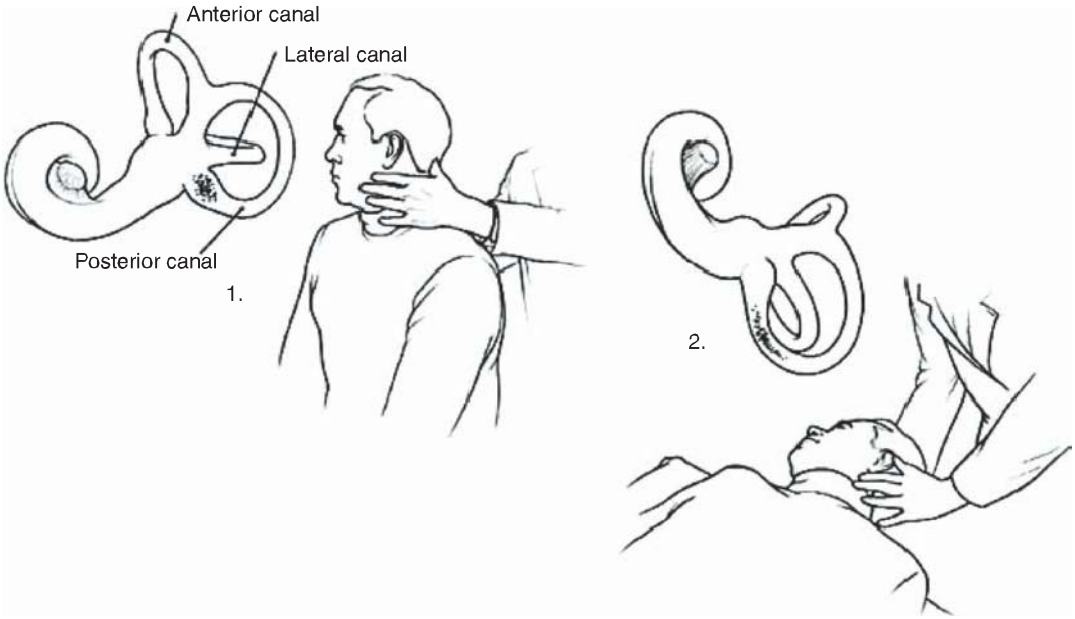

Figure 166.1 The Dix-Hallpike maneuver for identification of right posterior canal BPPV. The patient's head is turned 45 degrees to the right while sitting upright (*step 1*). Then lowering the patient to supine position with the head extended and still to the right (*step 2*) allows debris in the posterior canal to fall to a lower position in the canal. The resulting flow of endolymph away from the ampulla causes nystagmus due to deflection of the posterior canal cupula. From Hullar TE, Minor LB. The neurotologic examination. In: Jackler RK, Brackmann DE. *Neurotology*, 2nd ed. St. Louis, MO: Mosby, 2004. BPPV, benign paroxysmal positioning vertigo.

diagnosis of BPPV resulting from canalolithiasis of the posterior semicircular canal can be made with great clarity based upon the latency (2 to 10 seconds), duration (10 to 40 seconds), direction (upbeating with a torsional geotropic component beating toward the downward ear), and fatigability of the nystagmus upon repeated testing. The nystagmus with lateral canal BPPV is horizontal and may beat toward (geotropic) or away from (ageotropic) the downward ear. It often begins with a shorter latency, increases in magnitude while maintaining the test position, and is less susceptible to fatigue with repetitive testing than the nystagmus observed with posterior canal BPPV. If the nystagmus is geotropic, the particles are likely to be in the long arm of the lateral canal relatively far from the ampulla. If the nystagmus is ageotropic, the particles could be in the long arm relatively close to the ampulla, attached to the cupula, or on the opposite side of the cupula either floating within the endolymph or embedded in the cupula. This presentation is thus termed "cupulolithiasis." The difficulty in cases of cupulolithiasis arises in sorting out which horizontal canal (left or right) has the pathologic process because laying 70 degrees back toward supine with the head turned to one side will elicit ageotropic nystagmus whether the left or right horizontal canal is involved. The side that, when placed down, elicits greater symptomatic complaints and nystagmus amplitude is likely the provocative ear. These features can also lead to the nystagmus of horizontal canal BPPV being confused with a positional nystagmus arising from a central abnormality.

Canal repositioning maneuvers are designed to move otoconial particles from the semicircular canals back into the vestibule. The most commonly used maneuver to treat posterior canal canalolithiasis BPPV was described by Epley (128): Patients are first placed in the Dix-Hallpike position that provokes their vertigo; the head is then rolled 180 degrees in two steps until the affected ear is up; and finally the patient is returned to a sitting position (Fig. 166.2). Patients may experience a recurrence of their symptoms and require repetition of the Epley maneuver at home for several weeks. Other repositioning maneuvers, including the Semont liberatory maneuver and the Brandt-Daroff exercises have also been described for the treatment of BPPV that may not respond to the Epley maneuver, and specific maneuvers have also been described for the horizontal canals.

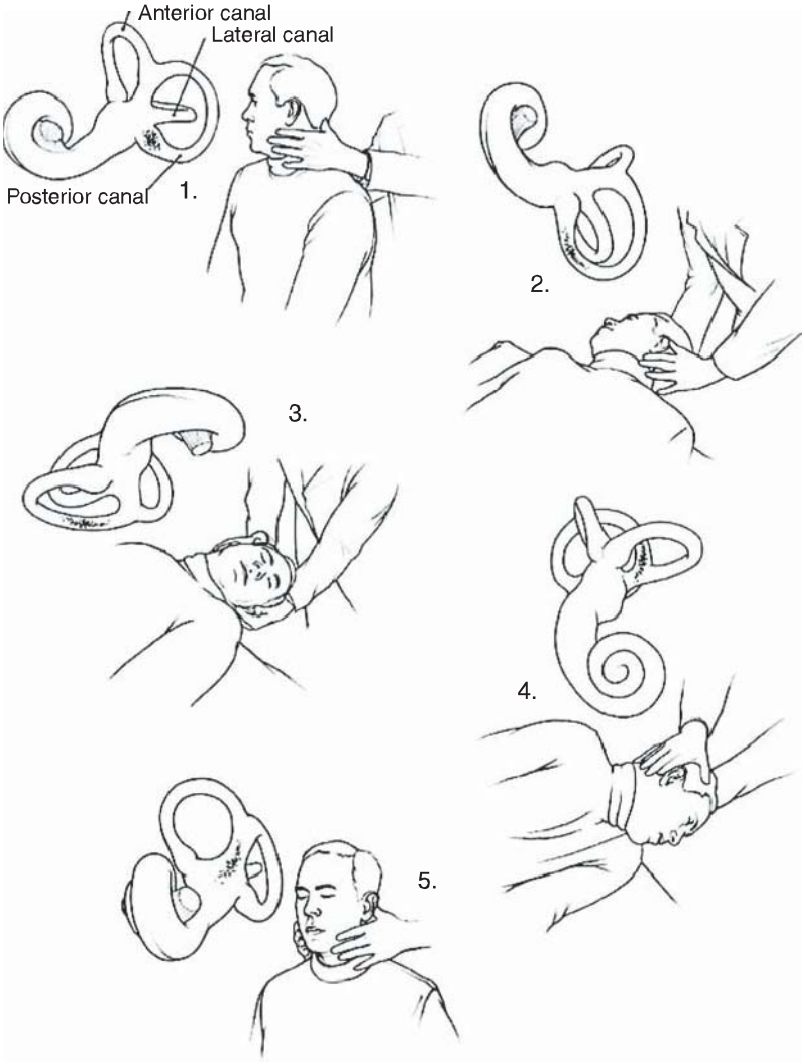

Figure 166.2 Canalith repositioning maneuver for treatment of BPPV affecting the posterior semicircular canal. In panel *1*, the patient's head is turned to the right at the beginning of the canalith repositioning maneuver. The **inset** shows the location of the otoconial debris near the ampulla of the posterior canal. The diagram of the head in each inset shows the orientation from which the labyrinth is viewed. In panel *2*, the patient is brought into the supine position with the head extended below the level of the table, that is, the Dix-Hallpike position as shown in Figure 166.1. The debris falls toward the common crus as the head is moved backward. In panel *3*, the head is rotated approximately 90 degrees to the left while keeping the neck extended with the head below the level of the table. Debris enters the common crus as the head is turned toward the contralateral side. In panel *4*, the patient's head is further rotated to the left by 90 degrees, rolling onto the left side until the patient's head faces down, and the debris begins to enter the vestibule. In panel *5*, the patient is brought back to the upright position, not turning the head until the patient is upright so that debris stays in the vestibule. Illustration by David Rini. From Hullar TE, Minor LB. Vestibular physiology and disorders of the labyrinth. In: Glasscock ME, Gulya AJ, eds. *Surgery of the ear.* 5th ed. Hamilton, ON: People's Medical Publishing House, 2003, Chapter 4. BPPV, benign paroxysmal positional vertigo.

Canalith repositioning maneuvers have been shown to control symptoms in over 90% of BPPV cases. However, a small fraction of patients continue to have refractory disabling vertigo despite multiple repositioning attempts. In these patients, surgical treatment may be considered. Section of the posterior ampullary nerve, also known as singular neurectomy, can be performed by accessing the singular nerve deep to the round window niche via a transcanal approach (129). More commonly, posterior semicircular canal occlusion is performed through a transmastoid approach, whereby the canal lumen is blocked, eliminating endolymph flow in response to the gravitational pull on canaloliths, but also dampening flow for most head movements that would normally excite the plugged canal (130).

Superior Canal Dehiscence Syndrome

In 1998, Minor et al. (131) described that dehiscence of bone overlying the superior semicircular canal can result in a clinical syndrome with symptoms and signs related to vestibular and auditory dysfunction. The vestibular abnormalities include vertigo and oscillopsia induced by loud noises or by stimuli that change middle ear or intracranial pressure. These patients may exhibit a Tullio phenomenon (eye movements induced by loud noises) or Hennebert sign (eye movements induced by pressure in the external auditory canal). They may also experience chronic disequilibrium. The auditory abnormalities include an apparent conductive hearing loss (manifested as an air–bone gap on audiometry that is not due to middle ear pathology), autophony, and pulsatile tinnitus.

The pathophysiology of SCD can be understood in terms of the effects of the dehiscence in creating a "third mobile window" into the inner ear, thereby allowing the superior canal to respond to sound and pressure stimuli (131). The finding that eye movements evoked by sound or by pressure stimuli are in the same plane as the superior canal of the affected ear was important in focusing attention on the superior canal as the cause of these abnormalities (131,132).

Clinical Features

In a study of 65 patients with SCD, the age range at the time of diagnosis was 13 to 70 (median = 41; mean = 43) years. The right ear alone was affected in 27 patients and the left ear alone in 23 patients; 10 patients had vestibular symptoms, signs, and CT findings indicative of bilateral SCD. Vestibular manifestations were present in 60 and exclusively auditory manifestations without vestibular symptoms or signs were noted in five patients (133).

The eye movements induced by sound and pressure stimuli have an important role in making the diagnosis (131,132). These stimuli often lead to nystagmus in SCD syndrome. The direction of the slow phase components of this nystagmus can be understood based upon the action of these sound and pressure stimuli on the affected superior canal. Loud sounds, positive pressure in the external auditory canal, and the Valsalva maneuver against pinched nostrils cause ampullofugal deflection of the cupula in the superior canal (Fig. 166.3). The nystagmus that is observed with these stimuli has slow phase components that are directed upward with torsional motion of the superior pole of the eye away from the affected ear. Conversely, negative pressure in the external canal, Valsalva against a closed glottis, and jugular venous compression can cause oppositely directed eye movements with slow phase components directed downward with torsional motion of the superior pole of the eye toward the affected ear.

Auditory symptoms and signs in patients with SCD have also been described (134,135). The Weber tuning fork test (512 Hz) typically lateralizes to the affected ear. Patients can experience symptoms such as hearing their pulse or hearing their eye movements, and their own voice may be perceived as distorted and too loud, a phenomenon known as autophony (136). An increased sensitivity to bone-conducted sounds, due to the low impedance for bone-conducted sound to enter the inner ear at the dehiscence, appears to be the mechanism responsible for the auditory symptoms in these patients.

Autophony can also be caused by patulous eustachian tube (137). A loss of tissue within the cartilaginous portion of the eustachian tube is thought to cause abnormal patency of the tube that results in abnormally loud perception of a person's own voice. The autophony associated with SCD tends to be unremitting from the time of onset, whereas autophony due to patulous eustachian tube may be more intermittent and especially position dependent. A further difference in the characteristics of autophony in the two conditions is that patulous eustachian tube results in autophony that is equally loud for the spoken voice and for breathing sounds, whereas autophony in SCD is typically absent for breathing sounds. Finally, on otoscopy or tympanometry patients with patulous eustachian tube who are experiencing autophony frequently will demonstrate excursions of the tympanic membrane synchronous with nasal breathing when sitting upright, especially if the contralateral nostril is closed.

Diagnostic Tests in Superior Canal Dehiscence Syndrome

Bone conduction thresholds on audiometry in patients with SCD can be less than 0 dB hearing level, that is, better than normal. An air–bone gap, therefore, can exist even when air conduction thresholds are in the normal range (134,135). These patients have heightened sensitivity for bone-conducted sounds, a phenomenon known as conductive hyperacusis. In many cases air-conduction thresholds are also elevated as well due to the loss of air-conducted sound energy at the dehiscence. The air–bone gap in patients with SCD is typically greatest at the lower frequencies (250 to 1,000 Hz).

Distinguishing an air–bone gap on audiometry due to SCD from an air–bone gap due to middle ear pathology is important in determining the appropriate

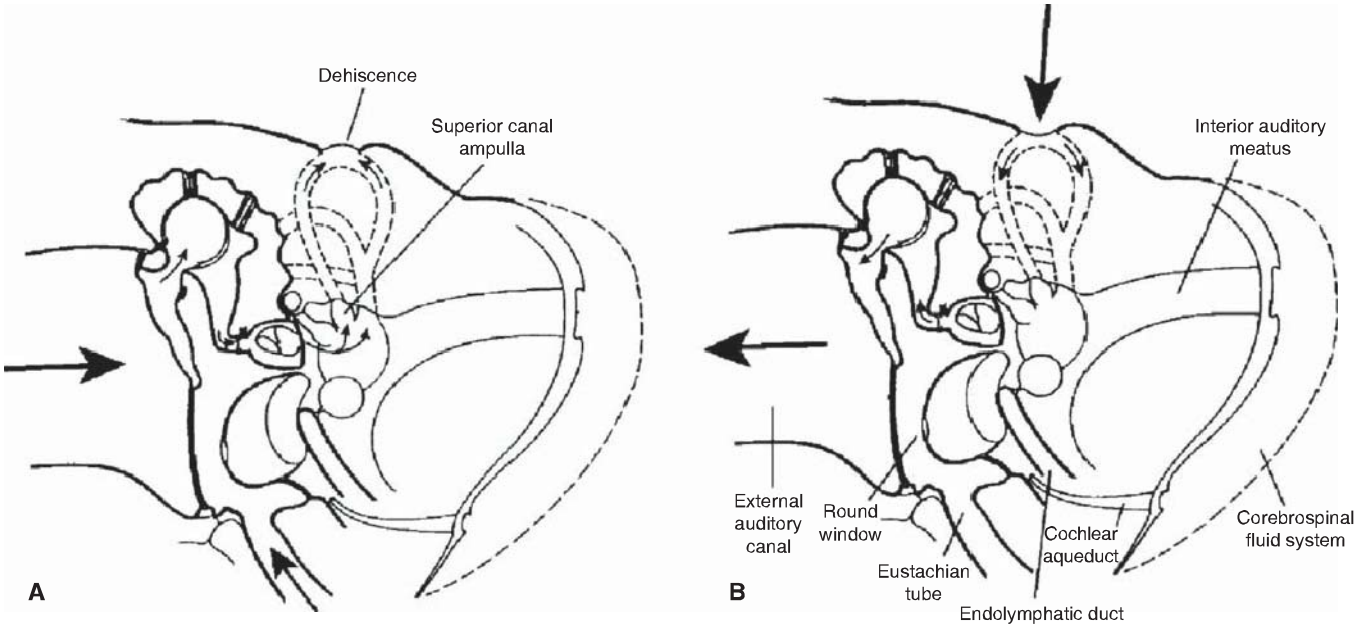

Figure 166.3 Schematic drawing of pressure changes in the middle and inner ear resulting from testing maneuvers in SCD syndrome. **A:** Sound, positive pressure in the external canal, or Valsalva maneuver against pinched nostrils move the stapes inward and result in ampullofugal endolymph flow with corresponding outward movement in the area of dehiscence. This results in excitation of vestibular-nerve afferents innervating the ampulla. **B:** Valsalva maneuver against a closed glottis, bilateral jugular venous compression, and negative pressure in the external canal result in inward movement in the area of dehiscence of the superior canal. Such pressure leads to ampullopetal deflection of the cupula and inhibition of the superior canal nerve afferents. Figure reproduced from Minor LB, Solomon D, Zinreich JS, et al. Sound-and/or pressure-induced vertigo due to bone dehiscence of the superior semicircular canal. *Arch Otolaryngol Head Neck Surg* 1998;124:249–258, with permission.

treatment options. Patients with an air–bone gap that was subsequently shown to be due to SCD but who underwent stapes surgery for presumed otosclerosis have been reported (134,135,139). Air conduction thresholds did not improve in these patients following stapes surgery. The acoustic reflex test provides a useful screening test in the identification of patients in whom the conductive hearing loss on audiometry may be due to SCD rather than to a middle ear problem such as otosclerosis. True fixation of the stapes should abolish the stapedial acoustic reflex response, whereas SCD causes conductive hearing loss but does not abolish the response. Patients with intact acoustic reflex responses and an air–bone gap on audiometry should undergo further investigation for SCD, such as a high-resolution CT scan of the temporal bones, before proceeding with surgical exploration of the middle ear.

Patients with SCDS typically have a lowered threshold for air-conducted sound to elicit the cVEMP from the ear affected by the disorder. They also have larger amplitudes for the air-conducted sound cVEMP as well as the ocular VEMP response from the affected ear (140–142). The "third mobile window" associated with the dehiscence creates a low impedance pathway that increases the sensitivity of vestibular receptors to sound and pressure stimuli. Assessment of air-conducted VEMP responses can be particularly useful in the search for the cause of an air–bone gap on audiometry. Conductive hearing loss caused by a middle ear abnormality typically results in the absence of an air-conducted VEMP response in the affected ear because the pathology decreases the amount of sound energy that is delivered to the inner ear. The presence of a VEMP response elicited at an abnormally low threshold in the setting of conductive hearing loss provides powerful evidence that middle ear mechanisms are not responsible for the air–bone gap.

High-resolution temporal bone CT scans have been used to identify dehiscence of bone overlying the superior canal. Patients with unilateral dehiscence are more likely to have thinning of the bone overlying the contralateral superior canal, suggesting an underlying developmental or congenital abnormality (143,144). Given that the onset of symptoms and signs of SCD typically occurs during adulthood, patients may develop the syndrome when an abnormally thin layer of bone is disrupted by trauma or eroded over time by pressure from the overlying temporal lobe.

Treatment

Many patients with SCD are not debilitated by the disorder and are able to avoid the stimuli that elicit the symptoms and signs. These patients may not need any specific treatment for the disorder. In other patients, symptoms such as sound- or pressure-induced vertigo, pulsatile oscillopsia,

and chronic disequilibrium may be disabling. Surgical repair of SCD is typically performed through the middle cranial fossa approach (131), although a transmastoid approach has also been described (145). The dehiscent superior canal is plugged with fascia and bone, thereby obliterating the canal lumen, and the bony middle fossa plate is resurfaced with bone cement. In our experience, plugging the superior canal has been more effective in resolving SCD symptoms than canal resurfacing alone (133), and studies have demonstrated closure of the air–bone gap and normalization of VEMP responses following plugging of a dehiscent superior canal (142,146).

Chronically Inadequate Vestibular Function

Chronic loss of vestibular function typically does not present with long-standing vertigo, which is indicative of episodic disruption or excitation of vestibular activity. Acoustic neuromas, for example, cause a slow progressive decline in vestibular function, and patients infrequently present with attacks of rotary vertigo. Patients with acoustic neuromas may exhibit hyperventilation-induced nystagmus (147), whereby patients breathe heavily for 30 breaths or 30 seconds, and a nystagmus with the fast phase beating to the side of the lesion can be observed. Proposed mechanisms for this effect include transiently improving conduction in a partially demyelinated nerve leading to a relative gain in function. Acoustic neuromas are more fully discussed in Chapter 159.

Bilateral Vestibular Hypofunction

The most common cause of bilateral vestibular hypofunction is exposure to intravenous antibiotics, specifically aminoglycosides. As mentioned previously, gentamicin is an ototoxic antibiotic that damages type I vestibular hair cells (51). Following peak and trough serum gentamicin levels as well as cumulative doses may prevent ototoxicity in some but not all cases. Ideally patients on gentamicin should have daily clinical assessments of their vestibular function (using head thrust testing or dynamic visual acuity) to identify any vestibulotoxicity as soon as possible (148), as immediately halting the aminoglycoside may preserve some function (Chapter 144). Patients with poor renal function or who are receiving concomitant ototoxic medications such as loop diuretics are at increased risk of vestibular loss. The A1555G mitochondrial mutation has also been shown to confer an increased risk of gentamicin-induced ototoxicity (149). Other causes of bilateral loss of vestibular function include genetic causes, exposure to radiation or chemotherapy, autoimmune mechanisms, bilateral Ménière's disease, and neurofibromatosis-2. Oscillopsia, or gaze destabilization with head movement and a sense of motion of objects that are stationary, as well as poor postural control and gait ataxia, are typical symptoms of bilateral vestibular hypofunction. It must be emphasized that these patients tend *not* to experience episodic vertigo. Central compensation for chronic peripheral vestibular loss occurs over time in most but not all patients receiving vestibular physical therapy (150). Because of the poor performance of other ocular reflexes (visual following, cervicoocular reflex, optokinetic reflex, etc.) at high frequencies, compensation can never fully restore visual stability for high acceleration head movements as may occur with unpredictable perturbations (e.g., stepping into a pothole while walking).

Vestibular rehabilitation, or vestibular physical therapy, is currently the primary treatment modality for bilateral vestibular hypofunction (151). The goal of vestibular rehabilitation is to foster compensation for vestibular loss (152). Patients are given exercises to induce compensation via three complementary approaches: *adaptation*, whereby residual vestibular mechanisms are trained to augment their level of functioning; *substitution*, whereby patients increase their reliance on other sensory inputs such as visual or proprioceptive cues to maintain balance; and *habituation*, whereby individuals learn to decrease their sensitivity to provocative stimuli (153). The efficacy of vestibular rehabilitation in reducing symptoms of vestibular dysfunction is supported by strong and consistent evidence (Chapter 168) (154). In the future, the multi-channel vestibular prosthesis currently under development may be of significant benefit to patients with bilateral vestibular hypofunction who do not have sufficient functional abilities after vestibular rehabilitation (155).

HIGHLIGHTS

- Ménière's disease is characterized by spontaneous attacks of vertigo, fluctuating low-frequency hearing loss, aural fullness, and tinnitus. Common laboratory abnormalities include a low-frequency sensorineural hearing loss, SP/AP ratio greater than 0.4 on electrocochleography, caloric weakness, and reduced VEMP responses. First-line therapy includes salt restriction and diuretics. Next, intratympanic steroid treatment may be beneficial. Chemical or surgical vestibular ablations are options in recalcitrant cases.
- Migrainous vertigo is a syndrome of episodic vertigo that lasts for minutes to days, and may or may not be associated with classic migraine headaches. Associated symptoms frequently include photophobia, visual motion sensitivity, and nausea. The diagnosis is suggested by a history of migraine headaches or a family history of migraine. Two theories have been proposed to explain migraine-associated vertigo: central electrical disturbances and peripheral trigeminovascular dysfunction. Treatment consists of avoiding dietary and lifestyle triggers, and the use of migraine prophylactic medications.

- Perilymph fistulas are known to occur following stapes surgery, temporal bone trauma, or in the presence of a labyrinthine fistula (e.g., secondary to cholesteatoma). Patients with a Mondini deformity are at increased risk. Both a sensitive diagnostic test for perilymph fistula and clear treatment guidelines are lacking, but the fistula test (observing for eye movements during pressurization of the external auditory canal) may be helpful.
- Vestibular neuritis is a syndrome of vertigo that lasts for days, and if there is associated hearing loss this is referred to as labyrinthitis. Vestibular neuritis likely represents a reactivation of a latent herpetic infection, usually of the superior vestibular nerve, associated with caloric weakness (superior nerve test) and preservation of the cVEMP (inferior nerve test). Steroids are the mainstay of treatment, and vestibular rehabilitation should be offered routinely.
- IMIED is a syndrome of inner ear inflammation resulting from autoimmunity. Patients present with fluctuating vertigo and hearing loss, often similar to Ménière's disease, though usually bilateral and with a faster decline in audiovestibular function in IMIED. Cogan syndrome includes IMIED associated with ocular inflammation—typically interstitial keratitis—and a systemic vasculitis. The presence of antibodies to a 68 kDa protein is suggestive of IMIED. The mainstay of treatment is initial steroid therapy followed by longer-term steroid-sparing immunosuppressive agents.
- BPPV is the most common cause of vertigo. It is due to ectopic otoconia free-floating in the endolymph (canalolithiasis) or, less commonly, lodged in the cupula (cupulolithiasis). The posterior canal is most commonly affected. The diagnosis can be made by observing an upbeating, geotropic nystagmus in the Dix-Hallpike position. The majority of cases resolve with canalith repositioning maneuvers such as the Epley maneuver.
- SCD syndrome is characterized by vertigo and oscillopsia induced by loud noises or stimuli that change middle ear or intracranial pressure, owing to a "third mobile window" created by the dehiscence. Patients may also experience autophony, pulsatile tinnitus, or conductive hyperacusis. Eye movements to provocative stimuli are in the plane of the affected superior canal. Testing abnormalities include a low-frequency air–bone gap on audiometry but with intact stapedial reflexes and lowered cVEMP thresholds and elevated oVEMP amplitudes. The diagnosis is made based on high-resolution temporal bone CT. Surgical plugging of the dehiscent superior canal is the most effective treatment.
- Bilateral vestibular hypofunction most commonly results from exposure to aminoglycoside antibiotics. The risk is increased in patients with poor renal function or who are using concomitant ototoxic medications such as a loop diuretic. Patients typically experience oscillopsia and chronic disequilibrium, *not* vertigo. Vestibular rehabilitation is the mainstay of therapy.

Central Vestibular Disorders

167

Gail Ishiyama *Akira Ishiyama*

A 48-year-old male has a 5- or 6-year history of gradually worsening gait disorder. He has had occasionally bouts of positional nystagmus that were called "benign positional vertigo." However, the modified Epley maneuver failed to resolve the positional nystagmus. He has noted increasing difficulty when walking, and recently he noted a clumsiness of his hands and arms. On examination, he has a downbeat nystagmus that is noted when looking down or to either side, and he has a saccadic pursuit. Coordination testing reveals dysdiadochokinesis and dysmetria of his extremities. He is unable to tandem walk and cannot stand in the Romberg position with eyes open or closed. A magnetic resonance imaging (MRI) demonstrates atrophy of the cerebellar vermis.

A 64-year-old woman has a history of the sudden onset of spontaneous vertigo with a persistent tilting of the body to the left as if pulled by a strong external force. She was completely unable to walk at the onset. She has a Horner's in the left pupil, large (hypermetric) saccades toward the left, and smaller (hypometric) saccades toward the right. She also had a skew deviation of the eyes with the left eye lower than the right and the upper poles rotated to the left. An MRI with diffusion-weighted imaging (DWI) was negative.

Both of these patients exhibit signs and symptoms of a central vestibular disorder. In this chapter, we discuss ways to distinguish central from peripheral vestibular disorders, the presentation of the common central vestibular disorders, the evaluation of a patient with dizziness, that is, the clinical examination, important questions to ask on history, and the audiologic and vestibular testing results in central vestibular disorders. In both patients, there are other neurologic symptoms noted in addition to the vertigo. Patient 1 has difficulty walking even when not having vertigo, and clumsiness of the extremities. Dysdiadochokinesis and dysmetria are cerebellar signs described below under cerebellar degeneration. Patient 2 has lateropulsion of the body (a sense of being pulled toward one side) and of the eye movements (bigger movements toward one side) associated with the vertigo.

From the history alone, there should be suspicion that these are not peripheral disorders. Patient 1 had been misdiagnosed with benign positional vertigo (BPV) on initial presentation, and patient 2 had been misdiagnosed with vestibular neuritis. Patient 1 had a history of cerebellar ataxia, and patient 2 had a history of a Wallenberg stroke. The negative MRI in a Wallenberg stroke may occur because the size of the stroke is too small to be detected. In central vestibular disorders, the inability to walk is oftentimes severe and cerebellar imbalance is often described as "clumsiness" or a "drunken feeling." The following chapter reviews the central and vestibular anatomy briefly, describes the specialized portions of the examination and history pertinent to evaluation of central vestibular disorders, and reviews the most common central vestibular disorders that may present to the otolaryngologist with complaints of dizziness.

THE CENTRAL AND PERIPHERAL VESTIBULAR SYSTEM

The peripheral vestibular system refers to the labyrinthine organs of the inner ear, which includes the end organs of the semicircular canals (cristae ampullares) and of the utricle and saccule (maculae) that contain the hair cells, and the innervating primary afferent neuron and nerve (Scarpa ganglia). The central vestibular system refers to the secondary vestibular neurons and their projections. The secondary neurons are the vestibular nuclei in the brainstem, divided into the superior (angular or Bechterew), the lateral (Deiters), the medial, and the descending (inferior or spinal) (1). In primates, the vestibulocerebellar and vestibuloocular connections are relatively more prominent in comparison with vestibulospinal connections. The

vestibular nuclei play a large role in central compensation after a peripheral labyrinthine injury.

Vertigo that is characterized by the sense of movement of the environment can result from lesions of the labyrinth, the vestibular nerve, or the interconnecting vestibular pathways in the brainstem and cerebellum. Vertigo is an illusion of movement, often of rotation, although the movement may be described as that of linear displacement (back and forth vertigo). Lesions of the labyrinth, the vestibular nerve, the vestibular nuclei, and the visual–vestibular interaction centers in the brainstem and cerebellum can produce a spontaneous vestibular nystagmus and vertigo. The production of spontaneous nystagmus requires an imbalance of tonic activity of the vestibuloocular pathways.

A lesion of the left vestibular labyrinth or nerve will produce a right-beating nystagmus with a torsional component. In lesions of the vestibular nuclei, the direction of spontaneous nystagmus that results is not as predictable and may be toward or away from the side of the lesion. Functional brain imaging demonstrates evidence for vestibular projections to the parietotemporal cortex and the thalamus in both normative controls and subjects with peripheral and central vestibular disorders (2). Because these vestibulo-thalamo-cortical projections do not carry tonic signals, a lesion in these cortical (within the brain) pathways will not produce vertigo but can produce an alteration of the body orientation (e.g., a sense of tilt or tendency to fall).

History of the dizzy patient: differentiating between a central versus peripheral cause of vertigo (Table 167.1). It is important for the clinician to distinguish the symptoms that the patient refers to as "dizziness." This distinction can be a clinical decision of critical importance. In evaluation of the patient with dizziness, the clinician must obtain as accurate and thorough of a history as possible to aid in distinguishing probable peripheral versus central causes. Dizziness may refer to a light-headedness that feels as if nearly passing out, near faint dizziness. Typical causes include orthostatic hypotension or cardiac insufficiency, for example, aortic stenosis. Oftentimes, dizziness due to cardiac disease will worsen with exertion, and is not characterized by vertigo. When the patient describes a sense of movement of the environment, the symptom of vertigo, it is strongly suggestive of an imbalance within the vestibular system. Vertigo can occur due to either a peripheral or a central vestibular lesion. Typically, vertigo is an episodic phenomenon, whereas a nonvestibular dizziness is more likely to be a continuous nonspecific type of dizziness. Episodes that occur only in specific places, such as walking through the store aisles, are highly unlikely to be vestibular, and are more likely related to anxiety syndromes or to a migraine-associated sensitivity to visual stimuli. Gait imbalance is often described as "dizziness," and the differential can include peripheral or central vestibular disorders, as well as neurodegenerative conditions such as Parkinson disease or spinal stenosis.

Peripheral and central spontaneous nystagmus (Table 167.2). Spontaneous nystagmus occurs when there is an imbalance of the tonic firing and signals to the oculomotor neurons. Spontaneous nystagmus is in reference to a nystagmus that occurs with the eyes in primary position, without any external stimuli. The primary position is the eyes looking forward in midposition, and the patient in the seated position. Positional nystagmus is nystagmus that is not present in the sitting position but is present in other head or body (e.g., head-hanging) position. Both spontaneous and positional nystagmus can occur secondary to either peripheral or central vestibular disorders.

The type of nystagmus can oftentimes localize the lesion. The vestibular system, both peripheral and central, is the primary source of tonic signals for most types of spontaneous nystagmus. A peripheral vestibular lesion, a lesion of the labyrinth or vestibular nerve, results in a spontaneous nystagmus with combined torsional, horizontal, and vertical components with predominantly a horizontal component. A lesion of the vestibular nucleus can cause a horizontal torsional nystagmus that appears similar to a peripheral nystagmus. However, the direction does not indicate the side of the lesion, and the nystagmus is not suppressed with fixation because of the damage to the visual–vestibular pathways (3).

Spontaneous peripheral nystagmus. Whether the lesion is of the labyrinth or the vestibular nerve, the type of nystagmus is invariable: horizontal, torsional beating toward the contralateral side, increasing in frequency and amplitude

TABLE 167.1 DISTINGUISHING CENTRAL FROM PERIPHERAL CAUSES OF DIZZINESS

	Nausea and Vomiting	Ability to Walk	Hearing Loss	Focal Neurologic Signs and Symptoms	Associated Autonomic Symptoms (Sweating, Pallor)
Peripheral	Severe	Unsteadiness but able to walk	Common	Rare	Pronounced
Central	Moderate	Nearly incapable of walking	Rare except AICA infarct	Common	Less pronounced

TABLE 167.2 DISTINGUISHING CHARACTERISTICS OF PERIPHERAL VERSUS CENTRAL NYSTAGMUS

	Type of Nystagmus	Effect of Fixation	Effect of Eye Position	Positional Nystagmus	Other Abnormalities on Testing
Peripheral: Labyrinth or vestibular nerve	Horizontal and torsional	Inhibited by fixation	Follows Alexander law	Latency, fatigues, torsional upbeat nystagmus, <1 min	May be associated with asymmetry of caloric response or of the VOR
Central: Brainstem or cerebellum or interconnections	Can be pure vertical, horizontal, or pure torsional	Unaffected by fixation	May be unidirectional, but if direction-changing is always central	No latency, does not fatigue, oftentimes downbeat or reversal of direction	Often associated with abnormalities of smooth pursuit, optokinetic nystagmus OKN, or saccades

on gaze to the fast component side, inhibited by fixation. A peripheral nystagmus is inhibited by fixation because the suppression requires an intact brainstem and cerebellum. The clinician should check that the nystagmus follows Alexander law: gaze in the direction of the fast component will increase the frequency and amplitude in a peripheral nystagmus, whereas gaze in the opposite direction will cause a decrease in the nystagmus (4). A peripheral nystagmus does not change direction with changes in eye position or with changes in the head or body position.

Spontaneous central nystagmus. The appearance of a central nystagmus can vary depending on the location of the lesion. Usually a central nystagmus will be prominent with or without fixation. Central spontaneous nystagmus occurs when there is an imbalance of the central vestibulooocular (VOR) or smooth pursuit pathways. In contrast to the peripheral vestibular pathways, the central horizontal and vertical pathways are separate, and thus a purely vertical or purely horizontal nystagmus is common in a central vestibular disorder. A central spontaneous nystagmus can be purely vertical, purely horizontal, or purely torsional, or some combination. Similarly to a peripheral nystagmus, gaze in the direction of the fast component may increase the amplitude and frequency of the nystagmus. However, gaze in the opposite direction will often cause a change in direction of a central vestibular nystagmus. A null region may be found several degrees off of the center beyond which the direction of the nystagmus changes. A direction-changing nystagmus is always central. An apparent direction-changing nystagmus can occur in one peripheral entity: horizontal variant of benign paroxysmal positional vertigo (5).

Positional nystagmus, central and peripheral disorders. A nystagmus that is triggered by a change in position can be either peripheral or central in etiology. BPV, a peripheral vestibular disorder due to loose otoliths, is by far the most common cause of recurrent attacks of positional vertigo. However, a positional nystagmus and vertigo can be due to a central vestibular finding. Common patterns of central positional nystagmus include a persistent downbeat nystagmus, or a horizontal direction-changing nystagmus. The patterns of nystagmus can appear similar to an anterior canal BPV, or a horizontal canal variant BPV, respectively. The common central disorders that present with a positional nystagmus that can mimic anterior (downbeat) or horizontal (direction-changing horizontal) nystagmus include Chiari malformation, tumors of the cerebellum or around the fourth ventricle, or spinocerebellar ataxia neurodegenerative conditions. There are no central vestibular disorders that induce a nystagmus that is characteristic of the classic and most common BPV, posterior canal BPV: a burst of upbeat, torsional geotropic nystagmus with a duration usually less than 30 seconds, and always less than 1 minute.

EXAMINATION OF EYE MOVEMENTS IN CENTRAL VESTIBULAR DISORDERS

The patient should be observed in all eye positions for nystagmus (a total of eight positions): gaze 30 degrees to the left and then 30 degrees to the right, and thereafter on upgaze and downgaze to the left, to the right, and at midline, with each position held for at least 20 seconds. Traditional terms used by otolaryngologists include the following: *First degree nystagmus* is present only on gaze in the direction of the fast component. *Second degree nystagmus* is present in the primary position (midposition, looking straight ahead). *Third degree nystagmus* is present even on gaze away from the fast component. These terms are most applicable to peripheral nystagmus patterns, and may not be relevant in central vestibular nystagmus. A peripheral nystagmus should not change direction with any positional change of the body or of the eyes.

Smooth pursuit, both horizontal and vertical, should be evaluated by having the patient follow the clinician's pen or finger. The patient should be able to follow the target smoothly, without repeated "stops" that would be indicative of a "saccadic pursuit." If the eyes follow the target

using a series of saccades rather than smoothly, then the central oculomotor pathway is unable to generate a smooth pursuit and is dysfunctional. A saccadic pursuit is nonspecific and can occur with normal aging, and is common in disorders such as multiple sclerosis (MS), Parkinson disease, or other neurodegenerative disorders. A severely saccadic pursuit may be seen in cerebellar conditions as in the 48-year-old patient initially described. Saccadic pursuit suggests central pathology.

Saccades. Saccadic eye movements are examined by asking the patient to fixate alternately between two fixed targets. The first target is usually in the primary position, "Look at my nose." Then, the patient is asked to look quickly to a target placed 15 degrees to the right, "Quickly look to my pen," and then placed 15 degrees to the left. Saccades that repeated "overshoot," for example, when attempting to look at a target on the right, the patient saccades further to the right, or "undershoot" is a sign of central vestibuloocular motor dysfunction (hypermetric or hypometric saccades, respectively), that usually localize to cerebellar or cerebellar peduncle lesions. Slow saccades may indicate a brainstem lesion, and delayed saccades can be seen in cerebral hemispheric lesions.

Saccadic intrusions include square wave jerks, ocular flutter, and opsoclonus. Saccadic intrusions occur when unwanted saccades disrupt steady fixation. A differential of these entities is beyond the scope of this chapter. All of these entities are associated with central vestibular pathology, and would warrant referral to a neurologic specialist. These entities are common with cerebellar lesions, progressive supranuclear palsy, Huntington disease, Friedreich ataxia, or paraneoplastic syndromes.

Ocular tilt reaction. If a normal subject tilts the head toward the right, then the eyes will reflexively counterroll and skew to allow for visual stabilization. Traditionally, a skew deviation, which clinically is described as a diplopia with two images split both slightly horizontally, and vertically, was considered to be a central finding. However, the ocular tilt reaction is a labyrinthine reflex, and can be seen by stimulation of the contralateral utricular nerve (6). The ocular tilt reaction can be seen in peripheral labyrinthine lesions (7), in which case the head tilt and lower eye are toward the ipsilateral lesion. An ocular tilt reaction can also be seen in lateral medullary infarcts (Wallenberg syndrome) (8), in which case it is also toward the ipsilateral side. In mesencephalic lesions (of the midbrain), the tilt is toward the contralateral side. Skew deviation and the ocular tilt reaction are noted following ablative procedures of the vestibular periphery (labyrinthectomy or vestibular nerve section) and in association with idiopathic sudden unilateral peripheral vestibular or cochleovestibular loss (9). This also can occur following resection of acoustic neuroma, another form of acute deafferentation. The skew deviation is often the earliest to compensate, disappearing within a few days.

Positional nystagmus. The patient should be evaluated for nystagmus in the head-hanging right and left (Dix-Hallpike maneuver). In BPV, the nystagmus fatigues, has a few seconds or more of latency, and will be a torsional upbeat nystagmus if the particles fell into the posterior semicircular canal. Positioning in a central positional nystagmus may induce a downbeat nystagmus that persists as long as the head-hanging position is held. Other central nystagmus include a direction-changing nystagmus or rebound nystagmus. Two positional maneuvers can be conducted. The Dix-Hallpike maneuver is conducted by placing the patient in right or left head-hanging position very quickly. In the side-lying test, the patient moves slowly into the side-lying position and then the clinician evaluates for a slow persistent nystagmus that would be indicative of a central vestibular disorder.

Fixation suppression means that the removal of ability to focus, as with Frenzel glasses, is associated with an increasing of the nystagmus. A peripheral nystagmus is usually inhibited by fixation. If Frenzel glasses are not available, the clinician can observe the nystagmus using an ophthalmoscope and covering the patient's other eye. If the nystagmus increases, then the nystagmus was inhibited by fixation, a characteristic of peripheral nystagmus.

Vibration-induced nystagmus. The other maneuver that can be used in the clinical setting is application of vibration to the mastoid, which can elicit a peripheral nystagmus in a compensated peripheral vestibulopathy from vestibular neuritis, Ménière disease, or anterior semicircular canal dehiscence (using vibration over the suboccipital cranium) (10,11).

Head-shaking nystagmus. The clinician should examine for head-shaking induced nystagmus. In this maneuver, the patient is asked to turn the head quickly from right to left about 20 times at 2 to 3 Hz, and the eye movements are then examined, ideally with the suppression of fixation using Frenzel lenses. Head shaking nystagmus indicates a latent asymmetry of the velocity-storage that can be due to a peripheral or a central vestibular disorder. In peripheral disorders, the nystagmus induced will be of the peripheral type: horizontal with a torsional component. In central disorders, the nystagmus induced can be vertical, downbeating or upbeating, or can be horizontal. In a study of 16 patients with lateral medullary infarction (vestibular nuclei infarction), a central vestibular disorder, head-shaking nystagmus was observed in 87.5%, and was ipsilesional in all cases. Even in patients with a contralesional nystagmus spontaneously, the head-shaking nystagmus was ipsilesional (12).

Spontaneous downbeat nystagmus. A downbeat nystagmus has a fast phase beating vertically downward and typically will increase in vertical amplitude with horizontal gaze deviation (13). A downbeat nystagmus is always a central vestibular nystagmus. Lesions of the uvula and flocculonodular lobes of the cerebellum in the monkey will induce a downbeat nystagmus (14). In humans, a downbeat nystagmus often localizes to the cervicomedullary junction, including the midline cerebellum (vermis) and associated

pathologies include cerebellar ataxias, vertebrobasilar ischemia (VBI), MS, and Arnold-Chiari (AC) malformation (15). AC is a malformation associated with increased pressure on the flocculonodular region of the cerebellum (see Arnold-Chiari malformation). Decompression surgery may allow for reversal to normal (13).

Other types of central vestibular nystagmus. Other pathologic nystagmus patterns include *gaze-evoked nystagmus*, which is seen when the patient tries to move eyes away from primary (midline) position. In normal subjects, a nystagmus can be seen at the outermost peripheral positions of gaze. This normal physiologic variant is termed, "end-point nystagmus" and is normal. Typically, physiologic gaze-evoked nystagmus can be distinguished from pathologic forms in that it has lesser amplitude and frequency, is unsustained, is relatively symmetrical, and is not associated with any other ocular movement abnormalities.

However, it has been noted that a gaze-evoked nystagmus can be seen in up to 50% of the normal population (16). Furthermore, a recent study evaluating 56 subjects for gaze-evoked nystagmus reported that normal subjects have a high incidence of physiologic gaze-evoked nystagmus at even smaller angles of gaze: 93% at extreme gaze, 73% at 40 degrees, 43% at 30 degrees, and even at the lowest angle tested 21% at 10 degrees (17). In the clinical setting, the most common cause of a pathologic gaze-evoked nystagmus is drugs such as phenobarbital, phenytoin, alcohol, and benzodiazepines. Central vestibular pathologies associated with a gaze-evoked nystagmus include MS and cerebellar atrophy, and these diseases would usually be associated with other eye movement abnormalities.

Rebound nystagmus. Rebound nystagmus is a type of gaze-evoked nystagmus that disappears or reverses as the lateral gaze is held. After an attempted prolonged eccentric gaze of 20 or 30 seconds, upon returning to the primary position, a rebound nystagmus appears with the fast phase toward the center and the slow phase toward the side of attempted gaze-holding. Rebound nystagmus usually indicates cerebellar pathology, such as olivopontocerebellar atrophy (18). Tumors at the cerebellopontine angle, such as acoustic neuromas, may cause a Bruns' nystagmus. This presents with a low-frequency, large amplitude nystagmus when looking ipsilaterally, and a high-frequency, low amplitude nystagmus when looking contralaterally. In a study of 984 patients with acoustic neuroma, Bruns' nystagmus was present in 11% and was associated with larger tumor size, with 92% of patients with larger than 3.5 cm tumor having Bruns nystagmus (19).

OTHER FOCAL NEUROLOGIC EXAMINATION FINDINGS IN CENTRAL VESTIBULAR DISORDERS

1. As noted above, a careful examination of eye movements is important.
2. Examine the patient for head tilt (seen ipsilateral to a Wallenberg infarct) and the body for lateropulsion (also seen in central vestibular disorders, such as ipsilateral to a Wallenberg infarct). The lateropulsion may be so severe that the patient is unable to stand, which would usually be an indication of a central vestibular disorder. There may be concomitant lateropulsion of the eyes, with larger saccades toward the ipsilateral lesioned side in Wallenberg syndrome (20).
3. Facial weakness (CN VII): a peripheral weakness will include the upper and lower facial muscles, whereas a central weakness will spare the upper facial muscles (i.e., raising the eyebrows). Of note, both a peripheral and a central type of facial weakness can occur in association with a Wallenberg dorsolateral medullary stroke.
4. Facial sensory loss (CN V): the clinician should check the upper (V1), mid (V2), and lower chin area (V3) for light touch using a cotton wisp, and temperature sensation using a cold tuning fork (can be cooled under water). Avoid the angle of the jaw as it is innervated by upper cervical roots. Although some clinicians recommend pinprick testing, patients may find it unpleasant. Initial examination with a cotton wisp and cold tuning fork serves as a screening evaluation for additional methods of physical examination. The clinician can also check the corneal reflex which tests V1 (afferent) and VII (efferent). Ask the patient to look up and toward the opposite side and using a cotton wisp, lightly touch the cornea. This should elicit a blink response, which should be consensual. An absent corneal reflex supplements the findings of a trigeminal sensory deficit.
5. Visual fields testing the temporal and nasal upper, middle, and lower quadrants of each eye. Most infarcts in the posterior cerebral artery distribution will cause a visual field deficit.
6. Crossed sensory loss: a key indication for brainstem involvement, for example, facial sensory loss on the side ipsilateral to the infarct and extremity sensory loss on the contralateral side. A crossed sensory loss often localizes the insult to the dorsolateral medullary (Wallenberg infarct), and can be variably associated with vertigo, ipsilateral Horner's, hiccoughs, and dysarthria and dysphagia.
7. Horner syndrome consists of miosis (pupillary constriction) and ptosis, secondary to loss of sympathetic innervation. The difference in pupil size is termed anisocoria. The clinician should evaluate the patient in relative darkness since the abnormal miotic (small) pupil cannot dilate properly in a low light setting. In the Wallenberg syndrome, the Horner syndrome is ipsilateral to the infarct. Because the sympathetic pathway in the brainstem is close to the spinothalamic tract (pain and temperature) for the contralateral body, Horner syndrome due to brainstem lesions is often associated with contralateral loss of pain and temperature.
8. Head thrust test or Halmagyi maneuver (21): when positive, patients will have catch-up saccade because

they are unable to keep their eyes on the clinician's nose when the head is rapidly, passively turned to the side with the lesion. In bilateral vestibulopathy (e.g., gentamicin ototoxicity), the test will reveal catch-up saccades to both sides. In a right-sided vestibular neuritis, there may be a catch-up saccade when the head is turned passively by the clinician to the patient's right side.

9. Romberg: ask the patient to stand with the feet together with eyes open and eyes closed. A positive Romberg occurs when the patient's imbalance significantly increases with eye closure. The accentuation of imbalance with eye closure is a sign of either vestibular imbalance or proprioceptive loss. A patient with a central vestibular disorder such as a cerebellar stroke will likely be unable to stand in the Romberg position (feet together) and will be unsteady whether the eyes are open or closed. Strictly speaking, the inability to stand with the feet together (Romberg position) with the eyes open, as well as closed, is not a positive Romberg.
10. Always ask the patient to try to walk. Patients with lateropulsion will lean strongly toward one side (usually toward the lesion). Severe lateropulsion that interferes with walking or standing is usually a sign of central vestibular disorder.
11. Tandem walk: when performed with the eyes open, tandem walking is predominantly a test of cerebellar function. Vision and proprioceptive (position sense) will allow for a relatively normal tandem walk in a compensated peripheral vestibular loss (e.g., vestibular neuritis in the past). An acute vestibular lesion will usually impair the tandem walk, even with eyes open. Patients with cerebellar lesions will oftentimes have a wide-based gait and are unable to tandem walk even taking a single step.
12. Testing for coordination (cerebellar or central vestibular pathways) and other clinical manifestations of cerebellar dysfunction.
    a) Hypotonia: a diminished deep tendon reflex, oftentimes more prominent in the upper extremities or a "pendular" reflex. After tapping the patella, the patient's leg swings to and fro like a pendulum. This sign is indicative of large cerebellar hemispheric damage.
    b) Dysarthria: a slurring of the speech, abnormal articulation, and prosody (rhythm) is common in cerebellar syndromes.
    c) Eye movements as noted above. Common cerebellar eye movement findings include downbeat nystagmus, hypermetric saccades, and rebound nystagmus.
    d) Ataxia: inability to coordinate movements of the voluntary motor acts, which err in rate, range, force, and duration.
    e) Appendicular coordination: *Finger-to-nose*. Ask the patient to touch the tip of the index finger to their nose with the eyes closed. *Finger-to-finger*. Ask the patient to touch the tip of their index finger to yours. An *intention tremor* is missing the target and increasing the amplitude of tremor as the target is approached. *Dysmetria* occurs when the patient overshoots or undershoots the target.
    f) Appendicular coordination: check *rapid alternating movements*, for example, turning the hand alternating palm and back of the hand or a rhythmic slapping of the knee. An inability to conduct rapid alternating movements smoothly is called *dysdiadochokinesis*.
    g) Appendicular coordination: check *heel-to-shin*. While lying down, ask the patient to "draw" a perfectly straight line with the back of the heel, up and down the opposite shin.
    h) Tandem walk: a sensitive but nonspecific test for balance. In central vestibular disorders, the patient may be completely unable to tandem, and when severe the patient may be unable to stand. Patients with spinal stenosis or strokes causing motor weakness would also be unable to tandem walk. Similarly, patients with neurodegenerative conditions such as Parkinson disease would be unable to tandem walk. The quality of the walk can provide clues to the etiology. Spinal stenosis may be associated with a "scissoring" quality of the walk, and Parkinson may be associated with a shuffling gait and a pill-rolling tremor.

ASSOCIATED SYMPTOMS IN CENTRAL VESTIBULAR DISORDERS

In central vestibular disorders, the symptoms associated with the vertigo or onset of imbalance will be dictated by the location of the pathology. Central vestibular disorders generally localize to the brainstem or the cerebellum. Clinical examples of central vestibular disorders that can present with vertigo and imbalance include Wallenberg syndrome (an infarct of the dorsolateral medullary), MS, brainstem tumors or encephalitis, cerebellar ataxias, AC malformation, and cerebellopontine angle tumors.

Important Questions to Ask the Patient

"Do you feel as if you are about to pass out?" This would be consistent with global hypoperfusion, which can occur in orthostasis, cardiac insufficiency, or vasovagal reactions.

"If you are seated still when the dizziness occurs, do you feel as if the world or you are moving?" This would be consistent with true vertigo.

"How long is the vertigo spell, and is the onset abrupt or gradual?" Vertebrobasilar transient ischemic attacks (TIAs) often present with vertigo of abrupt onset, lasting 3 to 4 minutes in duration. The duration of the vertigo is critical in determining the differential diagnoses (see Table 167.3).

TABLE 167.3 LENGTH OF VERTIGO IN COMMON VESTIBULAR DISORDERS

Length of Vertigo Spell	Vestibular Disease Process
Seconds, always less than 1 min	Benign paroxysmal positional vertigo (22)
Minutes: 3–4	VBI (TIA) (23,24)
20 minutes to hours	Ménière disease (25)
Days	Vestibular neuritis (26)
Varies; can be seconds, minutes, or days	Migraine-associated vertigo, vestibular migraine, migranous vertigo, migraine equivalent (27)

BOX 167.1 NEUROLOGIC REVIEW OF SYSTEMS

Have you experienced any of the following symptoms? Please check yes or no and indicate if constant or in episodes.

1. Double vision, blurred vision, or blindness
2. Numbness of the face or extremities
3. Weakness in arms or legs
4. Clumsiness in arms or legs
5. Confusion or loss of consciousness
6. Difficulty with speech
7. Difficulty swallowing
8. Pain in neck or shoulder

"Are the spells provoked by positional changes of the head?" BPV is characterized by spells of vertigo induced by tilting the head back or rolling over while prone. It is important to note that vertigo of any etiology is associated with increased sensitivity to head movement.

"Have you had loss of consciousness or confusion with the spells of dizziness?" Peripheral vestibular disorders are not associated with a loss of consciousness. Some patients may have a vasovagal response to the nausea and vomiting. However, sudden spells of falls with loss of consciousness would be characteristic of vertebrobasilar insufficiency, brainstem disorders affecting the reticular activating system, or as a diagnosis of exclusion, basilar migraine.

"In between the spells of dizziness or vertigo, do you feel imbalanced when walking or clumsy with your extremities? Some but not all cerebellar disorders are characterized by spells of vertigo. However, nearly all cerebellar disorders are characterized by persistent ataxia and/or clumsiness of the extremities. Notably, a cerebellar syndrome may affect the gait (truncal ataxia) without affecting the limbs (appendicular ataxia).

"Are there accompanying otologic signs with the spells of vertigo, such as aural fullness, hearing loss, or tinnitus?" These may indicate Ménière disease, but can also be seen in basilar migraine and TIAs in the anterior inferior cerebellar artery (AICA) distribution.

"Are there accompanying focal neurologic signs with the spells of vertigo, or in isolation?" (Box 167.1). The presence of focal neurologic signs would be highly suspicious for vertebrobasilar TIAs, indicating a high risk for stroke.

"Is there a personal history of hypertension, hyperlipidemia, diabetes mellitus, cancer, coronary artery disease, peripheral vascular disease, migraines with aura or complicated migraine, strokes or TIAs in the past?" Vascular risk factors should alert the clinician to the possibility of vertebrobasilar insufficiency as the cause of spells of vertigo. Additionally, chronic nonspecific imbalance may be secondary to microvascular ischemic changes in a patient with vascular risk factors. Both require evaluation with an MRI of the brain and preventative treatment.

Imaging modalities. There are now excellent noninvasive imaging technology to evaluate the cerebrovascular arteries including the vertebrobasilar arteries, and the arch of the aorta, and takeoff of vessels. Contrast-enhanced magnetic resonance angiography (CE-MRA) can identify arterial stenosis with nearly the same sensitivity as traditional cerebral angiography (28). MRI with FLAIR (fluid-attenuated inversion recovery) imaging is especially sensitive for demyelinating lesions in MS. A sagittal MRI that includes the posterior fossa is excellent to evaluate for AC malformation. DWI is highly sensitive to ischemia or infarcts (strokes), but can be negative when the lesion is small.

VERTEBROBASILAR ISCHEMIA AND INFARCTS

Vertebrobasilar TIAs are likely to recur and to progress to stroke. It is critical to recognize the first vertebrobasilar TIA. There appears to be as high or even higher risk of stroke after VBI TIAs than after carotid TIAs. Identifying a basilar stenosis is critical as there is a very high incidence of stroke or TIA recurrence (28). Referral to a stroke center is often indicated as interventions may range from anticoagulation, stenting, angioplasty, or clot retrieval angiography.

VBI is associated with the traditional vascular risk factors. If a patient presents with vertigo or hearing loss as a TIA, then the localization is in the posterior circulation, that is, VBI. The incidence of vascular risk factors in patients with posterior circulation strokes is high. In a study of consecutive patients presenting to a large stroke center, the New England Medical Center Posterior Circulation Registry, the group of patients with extensive atherosclerotic disease involving the basilar artery had a very high incidence of stroke risk factors. Hypertension was present in 70%, and coronary artery disease was present in 60%. The incidence of stroke risk factors was also high in 300

consecutive patients presenting with posterior circulation strokes or TIAs of any cause: 58% had hypertension, 25% had diabetes mellitus, 42% tobacco abuse, 33% had coronary artery disease, 19% had hyperlipidemia. Other important modifiable lifestyle factors included alcohol abuse (13%), obesity (11%), and use of oral contraceptive pills (2%). Hyperlipidemia was more common in intracranial vertebral artery disease and basilar disease (31% and 35%, respectively) in comparison with extracranial vertebral artery disease (18%) (23).

Isolated vertigo as transient VBI. Both the central and peripheral vestibular pathways are fed by the posterior circulation: the vertebrobasilar arteries. The vertebrobasilar system represents about 20% of cerebral blood flow, and posterior circulation TIAs and strokes represent about 20% of all TIAs and strokes. In fact, isolated spells of vertigo are likely the most common presentation of vertebrobasilar TIA first described by Williams and Wilson, 1962 (Table 167.4) (29). In that study, 48% of the patients with VBI had vertigo. In the guinea pig, occlusion of the internal auditory artery causes cessation of cochlear potentials and degeneration within minutes (30). However, clinically in humans, the predominant first symptom and most common symptom reported is vertigo. In a posterior circulation TIA, the onset of vertigo is usually very abrupt and spontaneous, rather than being induced by position, and there may be a flurry of spells within a few weeks' time. The duration of the vertigo is critical. In the case of VBI, the duration of vertigo is 3 to 4 minutes in length. A comprehensive discussion of this topic is provided by the authors in another reference (31).

Some neurologists have stated that isolated vertigo is an unlikely presentation of VBI given that there are multiple neurologic structures packed closely together within the brainstem, making isolated vestibular nuclei ischemia unlikely. However, the clinical data clearly demonstrate that isolated vertigo can be a TIA in the posterior circulation. Grad and Baloh (24) reported a high incidence of isolated vertigo in patients with VBI. Sixty-two percent had at least one episode of isolated vertigo, and in nearly one-fifth the first TIAs began with isolated vertigo. Since that report, there have been several studies demonstrating vertigo as the presentation and manifestation of VBI (32–34). It is important that clinicians and emergency room physicians are aware that transient VBI may not be evident on imaging studies, and oftentimes posterior circulation TIAs is a clinical diagnosis. In patients with VBI who had presented with vertigo, there was a high incidence of drop attacks: one out of three. There is also a very high incidence of visual symptoms of diplopia, field defects, or illusions. The visual illusions can mimic the visual aura of migraine (Table 167.5). In fact, transient ischemia within the vertebrobasilar system is a common cause of episodic nonpositional spontaneous vertigo spells in older patients.

For the clinician, there are distinguishing characteristics between the drop attacks of vertebrobasilar insufficiency and those of Ménière disease. VBI drop attacks are often described as "buckling of the knees" and a slowly crumpling downward. In a study of seven older patients with drop attacks of Ménière disease, also known as otolithic crisis, the attacks were described as forceful, and often violent, "as if being pushed by an external force." In many cases of Ménière drop attacks, there are associated injuries such as broken hip and concussions. In VBI, there may be an associated loss of consciousness. In Ménière drop attacks, there is never a loss of consciousness unless secondary to a concussion or head trauma (35).

Labyrinthine infarct. Pathologic studies following ligation of the internal auditory artery in animal studies demonstrate necrosis of the inner ear tissue with fibrous changes and osseous formation (36). Most cases of sudden hearing and vestibular loss have been associated with ischemia in the distribution of the AICA occurring with brainstem and cerebellar infarcts (37). In fact, isolated sudden

sensorineural hearing loss or vestibular loss (presenting similar to vestibular neuritis) can be the first presentation or sole presentation of an AICA infarct (see under AICA infarct). Sudden deafness has also been associated with fat emboli (38), thromboangiitis obliterans or Buerger disease (39), and macroglobulinemia (40).

Of note, a labyrinthine infarct is too small to be seen on MRI imaging. Differentiating a labyrinthine infarct, which is presumably an infarct in the labyrinthine artery, from a viral sudden hearing loss with vertigo can be difficult. We recommend obtaining an MRI with DWI and MRA to evaluate for potentially treatable vascular pathology (see Imaging Modalities).

AICA stroke and hearing loss and vertigo. The stroke patient who is most likely to present to the otolaryngologist and the stroke patient most likely to be confused for a purely peripheral inner ear disorder is the patient with a stroke in the AICA territory. The labyrinth is fed by the internal auditory artery, an end artery with minimal collaterals from the otic capsule. The internal auditory artery is usually a branch of the AICA. The internal auditory artery perfuses the cochlea and vestibular labyrinth, and occlusion of this artery causes hearing loss and vertigo. Internal auditory artery infarction occurs mostly due to thrombotic narrowing of the AICA or the basilar artery at or near the AICA orifice (41). In fact, sudden deafness and vertigo may be the sole presentation of an AICA infarct, and could be easily mistaken for a purely inner ear disease (42).

Of importance, in a study by Lee et al. (43), patients with prodromal audiovestibular disturbances had five times higher prevalence of focal or diffuse basilar artery occlusive disease near the AICA orifice, compared with those without prodromal audiovestibular disturbance (62% vs. 13%, $P < 0.001$). Given the low incidence of pure auditory or pure vestibular loss, the investigators speculated that internal auditory artery ischemia seldom results in selective involvement of the anterior vestibular artery or the main cochlear artery. Conversely, there should be strong suspicion for VBI if a patient presents with acute onset of combined auditory and vestibular loss, especially in a patient with vascular risk factors (43). This contrasts with viral vestibular neuritis, which presents with only minimal or no auditory symptoms.

In a study of 12 consecutive patients with MRI confirmed AICA infarcts, one-third had vertigo and/or auditory symptoms in isolated episodes from 1 day to 2 months prior to the AICA infarct, and notably 11 out of the 12 had sensorineural hearing loss (44). Audiometric data indicate cochlear pathology primarily as the cause of deafness. A recently published (Epub) study demonstrated abnormal cervical vestibular-evoked myogenic potentials (cVEMPs) in 8 out of 16 patients with AICA infarcts (50%), an indication of saccular pathology. The abnormal cVEMP was also associated with a caloric paresis and sensorineural hearing loss, suggesting that the audiovestibular periphery is a source of vertigo and hearing loss in AICA infarcts (45). The presence of hearing loss should be investigated in AICA infarcts as multiple publications have demonstrated this association (46,47). We recommend that any stroke or TIA associated with dizziness be formally evaluated with an audiogram as patients may be unaware of the hearing loss. We also recommend that sudden hearing loss with or without vertigo be evaluated by an MRI.

Traditionally, ischemia in the AICA territory is known to result in infarction of the dorsolateral pontomedullary region (brainstem) and the middle cerebellar peduncle. A complete AICA infarct is associated with the ipsilateral signs of a profound hearing loss, facial paralysis, cerebellar ataxia, loss of pain and temperature on the ipsilateral face, and contralateral pain/temperature loss on the body. In 82 consecutive AICA infarcts, the most common and dominant symptom was acute prolonged vertigo, lasting greater than 24 hours (98% of patients) (see Table 167.6) (43).

Posterior inferior cerebellar artery (PICA) syndrome or dorsolateral medullary syndrome: Wallenberg syndrome. An infarct in the PICA distribution causes a wedge-shaped infarct in the dorsolateral medulla, an area packed with salient neurologic nuclei. Therefore, the patient with a PICA infarct will usually have other neurologic signs. Of relevance to the otolaryngologist, in a study of 130 consecutive PICA infarcts without cerebellar involvement, only 57% presented with vertigo. However, 92% had gait ataxia, presumably from the infarct of the central vestibular nuclei and their interconnections (Table 167.7) (48). It is wise to look for a Horner's, a miotic pupil that does not dilate in darkness. The anisocoria (asymmetry of the pupils) of Horner's will be increased in darkness. In 88% of patients with Wallenberg syndrome, there was an ipsilateral Horner sign. Most of the patient exhibit severe gait ataxia. In the case report of three patients presenting with only vertigo and gait ataxia, which might be mistaken for a peripheral

vestibulopathy, the lateropulsion, a strong motor disturbance causing deviation of the trunk toward the ipsilateral side, was so strong that walking is severely impaired or impossible. The lateropulsion affects the oculomotor system, causing excessively large saccades toward the lesion, and abnormally small saccades away from the lesion (49). A PICA infarct, in contrast to vestibular neuritis, is associated with the severe motor disturbance that impairs the walking. In vestibular neuritis, the patient feels vertiginous and has some difficulty walking but will usually be able to walk. PICA infarcts, as opposed to AICA infarcts, do not present with auditory changes.

Cerebellar infarction. It has been stated that an isolated cerebellar stroke is likely sometimes mistaken for a peripheral vestibular neuritis. A recent study using MRI with DWI, a sensitive acquisition for recent ischemia, found that 75% (25 out of 33) patients with an apparent acute vestibular syndrome had a stroke, most often in the cerebellum. The study excluded patients with a recent viral illness (which occurs in about 30% of vestibular neuritis). Distinguishing characteristics of a cerebellar stroke were the inability to walk or stand, direction-changing nystagmus. Mild imbalance, characterized by the ability to stand and walk unassisted, but the inability to tandem walk, has been reported in an isolated superior cerebellar stroke (50). Cerebellar hemorrhages must be recognized promptly because of the possibility of herniation which can be fatal. A computed tomography (CT) scan can be obtained quickly, is readily available, and is highly sensitive to identify a cerebellar hemorrhage.

Vertebrobasilar ischemia and imaging. Given the similarity in presentation of some cerebellar symptoms, when seeing a patient with acute vestibular syndrome who has vascular risk factors, it is recommended to obtain an MRI with DWI. DWI may show abnormalities (hyperintense) in the first few hours after an acute stroke syndrome that does not show up on T2-weighted imaging for several hours (51). A large burden of microvascular ischemic changes on MRI, even with a negative DWI (negative for stroke) would be indication to minimize the stroke risk factors by controlling blood pressure, providing statins and an antiplatelet agent if there is no contraindication, and modifying lifestyle factors such as diet and tobacco and ethanol abuse. The specific treatment with regards to aspirin versus aspirin-dipyridamole versus anticoagulation should be determined by a specialist such as a neurologist, given this rapidly changing field. The other consideration in the setting of a potentially acute stroke is thrombolytic treatment at a stroke center, and in some cases of vertebrobasilar stenosis, stenting may be indicated (SSYLVIA study) (52).

MIGRAINE-ASSOCIATED VERTIGO AND BASILAR MIGRAINE

Episodic vertigo spells occur in about one-fourth of patients with migraine (53). Migraine is diagnosed by the severity of the headaches and the associated symptoms (Table 167.8). Vertigo attributed to migraine is also known as vestibular migraine, migraine variant, migraine equivalent, atypical migraine, migraine-associated vertigo, benign recurrent vertigo, and previously as vestibular Ménière disease. Acephalgic migraine or atypical migraine can also occur; in this case, the patient has symptoms attributable to migraine without any headache pain. Migraine-associated vertigo is the second most common cause of recurrent vertigo after benign paroxysmal positional vertigo, and migraine-associated vertigo likely accounts for 6% to 7% of patients in clinics managing patients with dizziness (54). Benign paroxysmal vertigo of childhood is likely migrainous vertigo and is associated with the onset

TABLE 167.8 DIAGNOSTIC CRITERIA FOR MIGRAINE WITHOUT AURA (INTERNATIONAL HEADACHE SOCIETY, 2004)

At least five attacks fulfilling B-D
Headache last 4–72 h (untreated)
Headache has at least two of the following:
- Unilateral
- Pulsating
- Moderate or severe (inhibits or prohibits daily activities)
- Aggravated by walking, stairs, or similar physical activities

During headache at least one of the following:
- Nausea and vomiting
- Photophobia and phonophobia

Other causes of headache have been ruled out

From International Headache Society, Headache Classification Subcommittee. The international classification of headache disorders, 2nd edition. *Cephalalgia* 2004;24:1–60.

TABLE 167.9A PROPOSED DIAGNOSTIC CRITERIA FOR *DEFINITE* MIGRAINOUS VERTIGO

Recurrent vestibular symptoms such as rotatory/positional vertigo, other illusory self or object motion, head motion intolerance
Current or previous history of migraine according to criteria of the International Headache Society, 2004 (59)
At least one of the following migrainous symptoms during at least two or more vertiginous attacks: migrainous headache, phonophobia, photophobia, scintillating scotoma, or other auras
Exclusion of other causes

From Lempert T, Neuhauser H. Migrainous vertigo. *Neurol Clin* 2005;23(3):715–730.

of migraine at a later age (55). The duration of vertigo in migraine-associated vertigo can vary from seconds to minutes and sometimes can last days and resemble recurrent vestibular neuritis (27). A study of 208 patients presenting to a neurotology clinic with benign recurrent vertigo demonstrated a comorbidity of migraine in 180 patients (87%) (56). Of these patients with both migraine and benign recurrent vertigo, 79% experienced the vertigo spells in isolation, unassociated with migraine symptoms. These patients would not meet the strict criteria for definite migrainous vertigo (54,57) (Tables 167.9A and 167.9B).

There is not a consensus regarding the strict definition of migrainous vertigo. Thus, a recent longitudinal follow-up of 75 patients was conducted to evaluate the reliability of diagnoses of definite or probable migrainous vertigo using the criteria of Lempert and Neuhauser (54). After a mean time of 8.75 years, definite vestibular migraine was confirmed in 85% of those previously diagnosed with definite vestibular migraine. Fifty percent of the patients with probable vestibular migraine evolved to the criteria for definite vestibular migraine, and 32% remained with diagnosis of probable vestibular migraine. Thus, there was very high reliability and validity of the diagnoses of probable and definite vestibular migraine. A subset evolved to have mild hearing loss, and thus met criteria for Ménière disease, but had symptoms atypical for Ménière disease (58).

Of the patients meeting the International Headache Society criteria for migraine (59), 62% of patients with migrainous vertigo met criteria for migraine with aura (56), and this percentage is significantly higher than the reported percentage of 28% of all patients with migraine that have migraine with aura (60). Migraine with aura appears to be associated with a higher frequency of infarcts than those with common migraine (migraine without aura). In the case of migraine with transient unilateral hearing loss and tinnitus as aura, the authors recommend the use of verapamil as the first-line agent, and agree that triptans would be relatively contraindicated (61). There may be a predominance of vertebrobasilar strokes associated with migrainous stroke. Bogousslavsky et al. (62) reported 9 posterior cerebral artery infarcts and 2 brainstem and cerebellar strokes among 22 migrainous strokes (41%), which is twice the ratio than general strokes of which posterior strokes reportedly represent 20% (62).

Basilar migraine. Basilar migraine is a subtype of migraine with aura characterized by recurrent headaches, oftentimes occipital in location, with focal neurologic symptoms localizing to the posterior circulation (Table 167.10) (63). The first attack in 65% of the cases was in the second or third decade. Commonly, patients with basilar migraine exhibit impaired consciousness (77%) and bilateral visual impairment (86%), as well as vertigo (63%). The impaired vision may be a blurring of the vision diffusely (69%) or flickering or wavy lines, called teichopsia (69%). The impaired consciousness ranges from coma (24%),

confusion (43%), or syncope (35%). Other associated symptoms include gait ataxia, paresthesias, dysarthria, and tinnitus. The prophylactic treatment of choice in basilar migraine is calcium channel blockers. Triptans and ergots are considered relatively contraindicated in basilar migraine. Because of the similarity in presentation between basilar migraine and VBI, evaluation of the cerebrovasculature with an MRI and referral to a neurologist are warranted.

Migrainous vertigo without other symptoms does not meet criteria for basilar migraine, and has been considered to be potentially responsive to triptans. In a trial with limitation mainly from too few subjects, zolmitriptan was not associated with significantly greater relief versus placebo for migrainous vertigo. However, the study was insufficiently powered (64).

Migraine-associated vestibulopathy, hearing loss, and motion sickness. There is evidence that migraine can be associated with hearing loss, tinnitus, and auditory end organ damage (61,65). Unilateral caloric paresis has been reported to occur in 18% to 21% of migraineurs with vertigo (27,66). Migraine is also associated with Tumarkin-like falls, sudden falls with no loss of consciousness described as "being pushed by an external force," originally described in association with Ménière disease. Tumarkin-like falls were associated with vestibulopathy as demonstrated on vestibular testing in migraine patients without Ménière disease (66). Migrainous vertigo is also associated with abnormalities in vestibular evoked myogenic potentials (VEMPs) (67). These findings indicate an association of peripheral vestibular damage with migraine. A recent pilot study reported that rizatriptan pretreatment was associated with a decrease in motion sickness induced by off-vertical axis rotation in migraine patients with motion sickness (68). The effect is proposed to be mediated by serotonin receptors within the serotonergic vestibular-autonomic pathways, a central vestibular mediated pathway.

Treatment of migraine-associated vertigo. In general, the prophylaxis of migraine-associated vertigo is similar to that to prevent migraine headaches. Medications commonly used include calcium channel blockers, tricyclic amines, beta-blockers, and anticonvulsants such as topiramate or valproate. In the authors' experience, the use of acetazolamide can be effective for both the audiovestibular symptoms and the headache, especially if the disease process mimics Ménière disease (aural fullness, tinnitus, and vertigo). In the case of migraine–Ménière's, the characteristic that distinguishes it from Ménière disease is the lack of progression of hearing loss. In these cases, the tinnitus and aural fullness are oftentimes bilateral. Preventative measures should also include lifestyle changes: regular exercise (which should be introduced gradually as acutely increasing exercise may trigger a migraine), regular meals, avoidance of high-fat and high-sugar foods, moderation of caffeinated beverages or ethanol, and avoidance of tobacco. Patients should evaluate for particular food triggers including red wine, processed foods, and artificial sweeteners. Dehydration can also trigger migraine headaches or vertigo spells. Women often present with migraine symptoms near the onset of menses. It is helpful for patients to keep a headache diary and to include in the diary any potential triggers.

MULTIPLE SCLEROSIS AND NEUROTOLOGIC SYMPTOMS

MS is a demyelinating disease of the central nervous system with onset usually in the third and fourth decades of life, with a female predominance (69). Because there is evidence that early treatment with disease-modifying agents can alter and slow down the progression of this disease, it is wise for clinicians to be able to recognize MS in order to refer patients to appropriate specialists. Immune-modulating agents include β-interferon, glatiramer acetate, and second generation MS treatments may include methotrexate, azathioprine, cyclophosphamide, mitoxantrone, and recently an oral agent, fingolimod (FTY720) (70). MS is the most common cause of acquired disability in young adults in the western world with an incidence of 4 to 8 newly diagnosed patients per 100,000 per year (71). MRI is the most sensitive imaging modality to identify demyelinating disease with attention to the fluid-attenuated inversion recovery (FLAIR) sequence, ideally including a sagittal image. Neurologists use MRI to follow the progression of MS disease, and enhancement with gadolinium can be used to evaluate for active inflammatory MS disease processes.

Neurotologic signs and symptoms of MS. Hearing loss occurs in about 10% of patients with MS with no apparent relationship between the severity of MS and the severity of hearing loss (72). The clinical presentation of the hearing loss in MS varies from acute to subacute (over months) to insidious with oftentimes a partial remission of hearing loss. Vertigo is the initial symptom in about 5% of patients with MS, and is reported to occur at some time during the disease in about half of patients with MS (69). The vertigo may be secondary to demyelination of the root entry zone of the vestibular nerve, the brainstem vestibular nuclei, or the cerebellum. An acute attack of MS may be treated with intravenous Solu-Medrol to hasten the remission of symptoms and signs, and lessen the inflammatory response. Prolonged vertigo spells should be treated with antiemetics and vestibular suppressants such as benzodiazepines. Of note, there may be a higher incidence of benign paroxysmal positional vertigo in patients with MS, which can be treated with the traditional Epley maneuver.

Examination findings in MS. MS will often be associated with eye movement abnormalities, including internuclear ophthalmoplegia (INO), saccadic pursuit. An INO will manifest with an inability to adduct (move medially) the affected eye, and a dissociated nystagmus when looking to the contralateral side. The pathology is located within the medial longitudinal fasciculus (MLF), which is commonly

involved in MS due to the length of the MLF. Because INO is common in MS and uncommon in other diseases, the presence of an INO should trigger an evaluation for MS (73). A history of optic neuritis is common in MS, which may be associated with a relative afferent pupillary defect. Other common findings include brisk deep tendon reflexes, ataxia or other cerebellar signs, and impaired vibratory and position sense. With regard to the neurotologic studies, VEMPs are abnormal in one-third of patients with MS (74).

Ataxia syndromes. *Friedreich ataxia* is the most common of the hereditary ataxias, with a prevalence of 2 per 100,000, which is equal to nearly all of the other dominant ataxias combined. Friedreich ataxia is a recessively inherited ataxia with presentation of progressive limb and gait ataxia, loss of position and vibration sense, onset before 25 years, and absent deep tendon reflexes in the legs. Of note, there is some variability in presentation. Friedreich ataxia is secondary to a GAA repeat in the gene frataxin, the product is a mitochondrial protein related to oxidative stress. Both auditory and vestibular loss occur commonly, but oftentimes late in the disease process (75,76). *Refsum syndrome* is an autosomal recessive ataxia syndrome characterized by retinitis pigmentosa, bilateral sensorineural hearing loss, cerebellar ataxia, and peripheral neuropathy secondary to a defect in lipid alpha oxidase.

Episodic ataxias (EA) are a rare group of disorders of the cerebellum. In general, there are episodes of ataxia with relatively normal spells in between. While these disorders are relatively rare, they may present to the otolaryngologist with complaints of "dizziness." The patient with ataxia may state that the spells are similar to the feeling of drunkenness, and they may describe a clumsiness of the extremities and slurred speech. Most of the EA are inherited and a family history should be obtained. MRI imaging of the brain and upper cervical cord can reveal a cerebellar vermis (midline) atrophy. Specific DNA tests are available for all of the trinucleotide repeat syndromes. A battery of tests can be ordered on a patient with a dominantly inherited spinocerebellar ataxia syndrome. Treatment is symptomatic. Acetazolamide is quite effective to prevent the episodic spells in patients with EA-2, and to a lesser degree, EA-1, starting with a low dose of 125 mg/d and working up to an average effective dose of between 500 and 750 mg/d (77). In EA-2, the spells of ataxia are often associated with vertigo, nausea, and vomiting. The nystagmus in between spells of vertigo/ataxia may be downbeat or gaze-evoked.

Other causes of cerebellar ataxia. Other causes include idiopathic degenerative ataxias, such as multiple system atrophy, ischemic or hemorrhagic strokes, toxins such as alcohol, heavy metals, or solvents, autoimmune conditions, and infections. Gluten ataxia occurs when gluten is ingested in a susceptible patient and is associated with antigliadin antibodies (78). The onset of gait ataxia may be insidious.

Paraneoplastic cerebellar degeneration usually presents subacutely, with the most commonly associated cancers being small-cell lung cancer, breast or ovarian cancer, and lymphoma. The presentation of subacute cerebellar ataxia should trigger an extensive workup including imaging, and oftentimes analysis of the cerebrospinal fluid (CSF) is warranted. Paraneoplastic cerebellar ataxia is most commonly associated with small-cell lung carcinoma but many other cancers have been associated with paraneoplastic cerebellar ataxia. The underlying tumor may be unable to be detected early in the presentation of paraneoplastic disease (79). Thus, a workup for an occult malignancy is warranted in any patient with subacute cerebellar degeneration and the serum should be evaluated for antineuronal antibodies (80,81). The common antineuronal antibodies associated with paraneoplastic cerebellar ataxia include anti-Hu, anti-Yo, anti-Ri (which often has a less severe course), anti-Ma, anti-Tr, anti-CV2, anti-GAD, anti-VGKC (voltage-gated potassium channel), and anti-VGCC (voltage-gated calcium channel). These serum antibodies are identified in about one-half of patients with paraneoplastic cerebellar degeneration. An intensive search for an occult malignancy must be conducted; the first imaging modalities usually include whole-body CT and/or total body positron emission tomography (PET).

Arnold-Chiari syndrome. AC syndrome is a congenital condition characterized by a defect of the skull base that causes a herniation of the cerebellum and/or brainstem into the cervical spinal canal. The onset of symptoms usually presents in the second or third decades. AC syndromes are classified into four types. AC-I is an anomaly of congenital cerebellar tonsillar elongation with displacement through the foramen magnum. Symptomatic AC-I may present with brainstem or cerebellar signs, including downbeat nystagmus, and ataxias. Of note, herniation greater than 12 mm was invariably symptomatic. However, nearly 30% of patients with tonsillar displacements ranging from 5 to 10 mm below the foramen magnum were asymptomatic (82). Osseous abnormalities are also common including basilar invagination. The tonsillar descent is best evaluated on a sagittal T1- and T2-weighted MRI scan, which is preferred over CT. Uncomplicated AC-I may present with ataxia of gait, vertical downbeating nystagmus, which patients may describe as "oscillopsia." This is described as a visual blurring that is worse when walking on hard surfaces or when shifting the gaze. Other common features include occipital and cervical pain, ataxia of gait, and blurred vision. In symptomatic AC-I, there is nearly always pathologic nystagmus. Surgical correction by suboccipital decompression of the foramen magnum can halt the progression due to the cervical medullary compression, and can sometimes reverse the neurologic symptoms and signs. Patients with rheumatoid arthritis may be especially susceptible to cranial vertebral anomalies, and a recent series of 45 patients surgically treated for rheumatoid arthritis and cranial settling had excellent outcomes (83).

Thiamine deficiency. Wernicke's can present with eye movement paresis (ophthalmoplegia), confusion, and ataxia of gait and stance. Truncal ataxia is typically significantly worse than appendicular ataxia (testing finger to nose or heel

to shin). Thus, imbalance and falls may be an early presentation of Wernicke's and may present to the otolaryngologist. Traditionally, clinicians associate thiamine deficiency with alcoholism, but thiamine deficiency is associated with bariatric surgery, chemotherapy, HIV, hyperemesis gravidarum, malabsorption syndromes, prolonged parenteral feeding, prolonged starvation, thyrotoxicosis, uremia, and cancers (84). Diabetics may be relatively susceptible to Wernicke's because insulin deficiency may cause a reduction in the rate of thiamine transport across the intestine (85). Pathologic changes are noted in the vestibular nuclei in thiamine-deficient monkeys (86). MRI may show FLAIR hyperintensities in the thalami, mammillary bodies, tectal plate, and periaqueductal area (87). However, diagnosis of Wernicke's should be a clinical diagnosis as the MRI is reported to have a sensitivity and specificity of 53% and 93%, respectively. Recovery is dependent on rapidness of institution of thiamine. Hundred milligram intravenous per day should be administered as a trial since oral absorption may be deficient, especially in gastrointestinal cancers. It is best to not wait for the thiamine levels as early treatment is important.

HIGHLIGHTS

- The history is critical in the evaluation of a patient presenting with dizziness or vertigo. Distinguishing the type of dizziness is crucial. Vertigo will present with a sensation of movement of self or the environment, and can be seen in both central and peripheral vestibular disorders.
- The characteristics of the spontaneous peripheral nystagmus in an acute vestibular syndrome are a horizontal torsional nystagmus which obeys Alexander law (increases in velocity and amplitude when looking toward the side of the fast phase) and is suppressed by visual fixation.
- Common central vestibular nystagmus patterns include downbeat nystagmus or a direction-changing nystagmus. A vertical nystagmus is always central in etiology. Central vestibular disorders are often associated with other abnormal eye movements including saccadic intrusions, abnormal saccades, and pursuit.
- VBI should be suspected in an older patient with vascular risk factors. Spontaneous vertigo with an abrupt onset and duration of 3 to 4 minutes is highly suspicious for VBI. Isolated vertigo can be a manifestation of a vertebrobasilar TIA. Because of the propensity for recurrence, prompt evaluation of the vertebrobasilar circulation is indicated using contrast-enhanced MRA and MRI. When MRI is contraindicated, a CT angiogram can be used. Treatment can include thrombolytic therapy, and in stroke centers other interventions include angioplasty, stenting, intra-arterial thrombolytic therapy, and the use of clot retrieval instruments.
- Sudden deafness or vertigo can be a symptom of ischemia in the AICA distribution. From one-sixth to one-third of patients who had an AICA infarct had a prodrome of vertigo or hearing symptoms in the 1 or 2 months prior.
- Migraine-associated vertigo or vestibular migraine is one of the most common central vestibular disorders presenting to the otolaryngologist. One-fourth of patients with migraine have vertigo. The duration of the vertigo can vary greatly. The Bárány Society and the International Headache Society consensus narrowed the diagnosis of definite vestibular migraine to cases having migraine features with at least 50% of the vestibular episodes (88). These criteria will likely have higher specificity, but lower sensitivity. Migraine can be associated with hearing loss, vertigo spells, Tumarkin-like falls, and BPV.
- Vertigo is the initial symptom in 5% of patients with MS and hearing loss occurs in about 10% of patients with MS. MRI with FLAIR is highly sensitive for demyelinating plaques. Other commonly associated findings include INO, optic neuritis, brisk deep tendon reflexes, and loss of vibratory sensation.
- AC-I is associated with suboccipital headache, vertigo which is oftentimes elicited by positional changes or changes of head movements, and visual complaints including blurred vision. Usually symptomatic AC-I will be associated with a pathologic nystagmus, oftentimes a downbeat nystagmus. MRI is useful to evaluate for the presence of AC malformation, and also to evaluate the volume of the posterior fossa and CSF flow dynamics. Surgical correction may halt the progression or even allow reversal of symptoms when diagnosed accurately.
- A common metabolic condition that may present with central vestibular findings is thiamine deficiency, or Wernicke encephalopathy. Ocular abnormalities, ataxia, falls, and memory impairment are common presenting symptoms. Rapid institution of thiamine can reverse the progression of the disease, which can be life threatening.
- Cerebellar syndromes often present with vertigo and ataxia. Cerebellar diseases are often associated with an abnormal nystagmus with common patterns being downbeat nystagmus or a direction-changing nystagmus. Laboratory investigations to consider include examination of the CSF, genetic panels, vitamin E, vitamin B_1, antigliadin antibodies, and evaluation for toxins. MRI is superior to CT to evaluate for cerebellar degeneration. Total body CT and/or PET may be indicated in subacute cerebellar ataxia to look for a primary tumor.

Vestibular Rehabilitation

168

Susan L. Whitney *Yael Raz*

Persons with vestibular disorders often present with complaints of dizziness, being off balance, and sometimes nausea and vomiting. They may also report falls as a result of their vestibular disorder. Dizziness is a very common complaint in an otolaryngologist's office. The diagnosis and management of persons with dizziness can be perplexing, since there are so many causes of dizziness. Medication-induced dizziness is very common as is dizziness associated with headache. Thorough history and examination, often with laboratory testing, are necessary to confirm the presence and nature of vestibular dysfunction.

Balance and dizziness disorders are generally considered to affect older adults (1), although younger people also encounter vestibular disorders (2). The prevalence of dizziness/vertigo in a 1-year period has been estimated to be approximately 29% in women and 17% in men within the German population (2). In a large US study (n = 5,086), it is estimated that 35% of people over the age of 40 have had vestibular dysfunction based on their ability to stand in modified Romberg on a firm and compliant surface, with active dizziness increasing the odds of falling by 12 (3). Of 546 persons presenting to the emergency room (ER) with no known cause for a fall initially, when probed, 80% had reported dizziness within the last 12 month (4), suggesting that the dizziness may be related to falls. Persons with vestibular disorders become concerned about falls, resulting in their being more sedentary and further increasing their risk of falling.

Nine percent of older adults seen for chronic medical problems in an outpatient geriatric setting for nonbalance or dizziness complaints had unrecognized benign paroxysmal positional vertigo (BPPV) (5). These older adults also had greater reports of falls and impairments of the activities of daily living (ADL) (5). Vestibular physical therapy has been used to improve balance, decrease dizziness, and improve quality of life in persons with BPPV and other central and peripheral vestibular disorders. There is mounting evidence that vestibular physical therapy is effective in the treatment of vestibular dysfunction in adults and children (6–68). Two Cochrane meta-analyses of 21 and 27 randomized trials suggested that there was moderate to strong evidence to support that vestibular rehabilitation is a safe and effective intervention for persons with peripheral vestibular disorders (38,39).

Vestibular disorders are most commonly treated by physical therapists. Other health care providers such as occupational therapists and audiologists also deliver interventional care. Knowledge related to the treatment of BPPV is commonly taught within physical therapist curricula. Standards related to the knowledge base that is critical for the identification and treatment of vestibular disorders have recently been published (69). The newly published international guidelines written by a Barany Society subgroup provide a starti ng point for therapists to determine what additional knowledge they should acquire in order to optimally treat persons with balance and vestibular dysfunction (69). The treatment of vestibular disorders in many physical therapist curricula is considered advanced knowledge beyond an entry level doctor of physical therapy degree program. Any physical therapist who is a neurologic clinical specialist should have background in specific examination and intervention techniques for persons with vestibular disorders.

Developing a relationship between physicians and physical therapists interested in treating patients with vestibular disorders is important for the patients' optimal recovery. Good communication will enhance the care that patients receive and should ultimately speed their recovery. As a physician initially seeking referral to a physical therapist, it is reasonable to ask the intended provider what his or her experience is with the treatment of persons with balance and vestibular disorders. There are advanced training options that could also further develop their skills and experience in the treatment of persons with balance and vestibular disorders if they were interested in learning more.

Medications rarely help with persons with peripheral vestibular disorders, except in the acute phase. However, chronic use of medications is often beneficial in persons with Meniere disease for long-term symptom control. As persons improve, it is optimal to taper and stop the antidizziness and antinausea medication as it may actually slow down central compensation and the recalibration process of the vestibuloocular reflex (VOR). Long-term use of antidizziness medication is not advised, especially in older adults. The drowsiness often associated with the antiemetics and vestibular suppressants might increase an older adult's risk of falling. Vestibular suppressants, which are typically used to manage symptoms in persons with acute vestibular disorders, may slow vestibular compensation (70). Venosa and Bittar (71), in a prospective trial, suggest that persons who performed exercises acutely (symptoms that began less than 5 days prior to the start of the study) were less likely to use medication at 3 weeks than those who were not provided vestibular exercises. Patients in the vestibular exercise group had a greater number of normal Fukuda step tests and normal post head shake testing. Three weeks post exercise, 13% of the vestibular exercise group and 82% of the control group were taking medication daily (71). Medication for central vestibular disorders is effective (70).

Early vestibular exercises in persons with an acute vestibular disorder resulted in better Dizziness Handicap Inventory (DHI) scores (72), less anxiety, less reliance on visual cues, and better gait (73). Quality of life scores, as measured by the Medical Outcomes Study Short Form 36, improved after vestibular rehabilitation in persons with acute vestibular disorders (8,52). Perceived dizziness also has been noted to improve after a trial of vestibular physical therapy (52). Animal studies have suggested that there may be a critical period whereby immobilization had a negative impact on recovery from a vestibular deficit (74,75). People with peripheral vestibular disorders who underwent balance exercises within 6 months of onset had much better disability scores than those who presented after 6 months (8).

Dizziness severity and quality of life measures were predicted by when the balance exercises were initiated, with earlier onset relating to less dizziness and better quality of life measures (8). A delay in the onset of Cooksey-Cawthorne (vestibular) exercises led to worse scores in all cases studied, and late onset of exercise was considered to be a negative predictor for recovery (8). Early exercise in persons with peripheral vestibular disorders resulted in fewer symptoms at 3 weeks compared to a no-exercise control group (66,73). Also, people with late intervention for BPPV were more likely to experience residual dizziness within a 3-month period (76).

In summary, early exercise appears to decrease dizziness, prevent long-term complications such as anxiety, improve quality of life, possibly decrease the patient's chance of falling, and improve balance confidence. In addition, customized exercises appear to be more effective than a generic exercise program or no exercise (28,77). Acute physical therapy intervention for the person with dizziness and balance dysfunction appears to be a safe and efficacious treatment for persons with vestibular disorders (39,66).

VESTIBULAR REHABILITATION

After the person presents to the physical therapist, an in-depth examination begins with a thorough history of the dizziness. Just as in the physician's examination, the history is critical for the physical therapist in determining the optimal interventions. Sharing pertinent health information, examination results, and laboratory findings with the treating therapist will expedite and enhance patient care. Typically, the therapist will ask the patient questions regarding the frequency, duration, timing, and intensity of the symptoms; other comorbid medical conditions; medications; requirements of work; and living status (78).

Positions or movements that increase or decrease symptoms are very important in developing the treatment plan for the person with a vestibular disorder. Often, questions are asked related to movements that increase dizziness such as bending, getting out of bed, or even walking in a grocery store. A quick neurologic exam is also performed to assess the integrity of the smooth pursuit and saccadic eye systems and cranial nerves III, IV and VI. The integrity of the VOR, VOR cancellation, and the vergence system are also clinically assessed. The therapist may perform the head thrust test (79–85), dynamic visual acuity (35–37,85–90), and vibration-induced nystagmus test (91–94). All of the above assist the therapist in treatment planning and determining if additional testing is required as some patients may be self-referred or have not seen an otolaryngologist prior to seeing the physical therapist.

Strength, range of motion, sensation, and coordination are assessed at baseline. Range of motion of the cervical spine is particularly important to determine prior to performing the Dix-Hallpike maneuver. The physical therapist performs the Dix-Hallpike and the roll test ideally with infrared goggles, to determine if the patient has BPPV. If the Dix-Hallpike or roll test are positive, the appropriate canalith repositioning maneuver (CRM) will be performed based on the patients health and medical comorbidities.

Balance testing is an integral part of the typical physical examination including Romberg, semitandem standing, and tandem standing. Semitandem standing consists of having the patient stand with one foot in front of the other but not heel to toe. It is a transitional balance test between standing feet together (Romberg position) and heel to toe (tandem standing) and is often a difficult position for older adults to maintain. The patient's gait, as described above, will be assessed, and determination will be made whether an assistive device is in order to improve gait and safety. An attempt is made to avoid providing an assistive

device unless it is necessary, as many older adults will never stop using the assistive device once it has been prescribed. Persons who often do need an assistive device are those with bilateral vestibular loss because they fall frequently (95), especially on uneven surfaces or low light/no light conditions. If the person is very frail and afraid of falling, occasionally a rollator walker will be suggested. Rollators have four wheels, brakes, and a seat. The rollators allow patients to walk safely at a much faster gait speed than a standard walker. Gait speed has been shown to be an overall indicator of health (96). Walking at a more normal speed may have long-term cardiovascular and respiratory benefit. Standard canes are also used to provide support for persons with vestibular disorders and have been shown to decrease postural sway (97).

Once the examination is complete, the physical therapist will develop a plan of care. Patients are seen anywhere between one and three times per week, with frailty, depression, light sensitivity, a history of migraine, fear of falling, and anxiety being important factors in how often the patient is seen. Persons who are afraid to exercise, who are depressed, or very anxious may be unable or unwilling to perform the exercises at home without supervision/encouragement.

Patients are provided with written home exercises to perform between visits in order to speed their recovery. Typically the number of exercises provided is kept within reason, as patients often have difficulty finding the time to perform the exercises at home, especially if they are currently working. Often the therapist will attempt to build the exercise program into the patient's daily routine, such as standing on one leg while washing the dishes. Even retired adults will complain if it takes too long for them to perform the home exercise program, so patient education and negotiation is often required in order to have the patient "buy into" performing the exercise program at home. The therapist attempts to "dose" the exercises appropriately so that the movements increase the patient's symptoms, yet do not disable them.

If the exercise prescription is too aggressive, the patient will become too dizzy or might become fearful of the falling during the exercise and will stop performing the exercises. If the program is too easy, it will not be effective at maximizing the patient's recovery. Therapist experience and dialogue with the patient will maximize the interaction resulting in an exercise program that is individualized and appropriate for the patient. Individualized exercise programs appear to be superior to generic exercise programs and better meet the needs of the patient (77).

Exercises consist of eye/head movements in every conceivable position progressing to gait, exercises that incorporate head movements during gait, and standard balance exercises. Most people are asked to begin a walking program in order to increase their endurance, strength, and tolerance to movement. Exercises can be simple or very complex. A simple example might include having a person stand on one leg progressing to standing on one leg while tossing a ball or moving the head to the right and left following a moving target with the eyes and/or head. Exercises are individualized based on the patients' comorbid medical conditions and physical/mental health.

COMMON OUTCOME MEASURES UTILIZED IN VESTIBULAR REHABILITATION

The DHI is often used to quantify subjective impairment and to report changes over time in the self-perceived handicapping effects of dizziness (72). Scores range from 0 to 100 with 0 the best score and 100 the worst score possible. Change of 18 or more has been suggested to be clinically significant (72). Scores of greater than 60 on the DHI have been related to increased reports of falling (98).

Balance confidence is also frequently reported as an outcome measure. Generally when patients feel less dizzy and have better self-reported dizziness, they are better. The Activities-specific Balance Confidence (ABC) scale is the most commonly used balance confidence measure used with persons with dizziness (99). For the ABC scale, a percentage score is reported that ranges from 0% to 100% with 100% the best score and 0% the worst score. Scores of 67% or lower on the ABC appear to represent significant fall risk (100).

Verbal and visual analog scales (101) are also frequently reported as outcome measures, which should improve as the patient begins to feel better (less dizziness, improved balance, and better quality of life). The analog scale scores can be compared across time to suggest that the patient is feeling worse, the same or better as a result of the intervention.

Measures of gait and balance often used include the dynamic gait index (DGI) (102), gait speed (96), the functional gait assessment (FGA) (103,104), the clinical test of sensory integration and balance (CTSIB) (105), the Timed Up and Go test (TUG) (106,107), the five times sit to stand test (FTSST) (108), and simple measures such as timed standing in Romberg, single-leg stance or tandem Romberg (67,78). The DGI includes eight walking tasks, two of which require head movements in the pitch and yaw planes. Scores are based on an ordinal scoring algorithm with 24 the optimal score. Scores of 19 or less have been related to increased fall risk (109,110).

Gait speed is probably the best overall gait measure, as slower gait speed has been related to increased mortality and morbidity and shortened life expectancy (96,111). According to Studenski et al. gait speed, age, and gender are the optimal combination for predicting life expectancy. Patients who walk slower are also at greater risk for falling. Often one of the goals of the physical therapist intervention is to increase gait speed.

The FGA includes many of the original DGI items but was designed to be more difficult with the inclusion of

walking with eyes closed, walking backward, and walking heel to toe. Scores on the FGA vary between 0 and 30 with 30 the optimal score. Scores of ≤22 demonstrated the optimal sensitivity and specificity for fall risk (103). Scores ≤22 indicate that the person is at risk for falling.

The modified CTSIB is often performed in the physician office as well as by the physical therapist to determine fall risk and to assess vestibular function (112,113). The modified CTSIB includes standing in the Romberg position eyes open and closed plus standing on foam eyes open and closed (114). Persons who fall on foam are more likely to fall when walking on uneven surfaces. The modified CTSIB should be performed with caution because many patients fall off the foam. Careful guarding is required in order to assure that the patient and physician are safe while performing the examination. Cass et al. (114) suggested timing how long the person can maintain each of the four positions.

The TUG is a simple measure of balance that has been related to increased fall risk. The patient stands from a chair with armrests upon command and is asked to walk at their normal pace 3 m, turn, and return to sitting in the chair. Scores of 13.5 seconds or longer have been related to falling in older persons (115), and a score of 11.1 seconds has the optimal sensitivity and discriminative properties in persons with vestibular disorders (107). The TUG is extremely easy to test because one only requires 3 m of space, a chair with armrests, and a stop watch. Patients can perform the test with an assistive device (cane, walker). Generally, persons who present to the clinic with a cane or walker are more likely to have fallen, so careful guarding is advised in examining those patients who present with an assistive device.

The FTSST has been used to determine lower extremity strength and balance in persons with vestibular disorders (108). They are asked to stand as quickly as they can five times from a standard height chair (116). The test provides a good overall measure of function (116), especially in older persons with vestibular disorders.

Factors That Might Affect Recovery

Age does not seem to specially relate to recovery after vestibular insult. In a study by Jung et al. (117) persons over the age of 70 with dizziness complaints either received vestibular exercises (n = 103) or no treatment (n = 46). Significant improvements in dizziness and balance confidence were noted in the treatment group at both 3 weeks and at 3 months compared to the no intervention group. Comorbid factors often associated with aging such as diabetes, peripheral neuropathy, macular degeneration, glaucoma, impaired sensation, or restricted ability to move may affect compensation and recovery. Other factors not associated with aging that can also slow or hinder rehabilitative progress includes former eye surgery, a strabismus, a history of migraine, use of vestibular suppressants, avoidance behavior, and certain psychiatric conditions (obsessive compulsive disorder, anxiety) (8,118–121).

Persons with migraine may have difficulty with fast head movements and become nauseous more quickly than others. A history of motion sickness early in life may be associated with subsequent migraine. Persons who are prone to motion sickness often have more difficulty performing eye/head exercises. Care must be used in order to dose the intervention to allow for adaptation but to prevent the person from becoming ill with nausea, dizziness, or vomiting during or after the exercises. People who are afraid to move are also more difficult to treat, as exercise and movement appear to be the most efficacious way to promote recovery in the person with a vestibular disorder.

Persons with anxiety can be a challenge to treat. Psychologic factors appear to influence how people respond to and perceive dizziness (122). Anxiety appears to increase dizziness and distress, especially with movement. Fear of being dizzy and anxiety can trigger autonomic reactions that are very disturbing to the patient including increased heart rate and sweating. It appears that there is a link between anxiety and dizziness (123), with anxiety increasing the patients' symptoms. At times, psychotherapy and vestibular rehabilitation are combined for optimal effectiveness. Cognitive behavioral therapy has also been shown to be effective in decreasing dizziness symptoms in persons with chronic uncompensated peripheral vestibular disorders (41).

PERIPHERAL VESTIBULAR DISORDERS

Benign Paroxysmal Positional Vertigo

In the case of BPPV, repositioning maneuvers are effective, improve quality of life, and improve gait speed in people, especially older adults (124,125). Those who had late intervention for their BPPV were more likely to experience residual dizziness within a 3-month period (76). Although BPPV often resolves within a median of 2 weeks (126), sick days, physician visits, and interruption of ADL were frequently reported (126). In some patients with BPPV, use of the CRM is the only intervention that is effective. It is unusual but we have seen people who have had BPPV for over 20 years without relief of symptoms before the appropriate diagnosis was made and treatment provided. The financial costs to make the diagnosis of BPPV can be very high. In 2000, the average cost to make the diagnosis of BPPV was $2,684 (127). Polensek and Tusa (128) reported that the number of diagnostic tests to identify BPPV had not changed even with better education about vestibular disorders, but costs had increased between 2003 and 2008. Based on two recent practice guidelines by the Academy of Head and Neck Surgery and the Academy of Neurology, repositioning maneuvers for BPPV are very effective and safe (68,129). Thus, rendering a correct diagnosis quickly with appropriate treatment obviates costly and prolonged testing.

The Epley maneuver has been clearly illustrated by Furman and Cass (130) and can be quickly performed in the office setting after a positive Dix-Hallpike maneuver had determined the involved ear. The Epley maneuver involves rotating the head 45 degrees to the involved side and extending the head 20 to 30 degrees over the edge of a bed or table. The persons head is then rotated 90 degrees to the opposite side while maintaining neck extension, then rotated toward the floor, and to complete the maneuver the person is sat up. Each position is generally maintained until the nystagmus stops. Posttreatment instruction, including head restrictions, do not appear to affect outcome as reported in a recent meta-analysis (131).

BPPV is commonly seen in older persons. Imai et al. (132) reported that the mean age of their subjects (n = 108) was in their sixth decade of life. Seventy-seven percent of their subjects were between 51 and 80. In persons with posterior canal BPPV, it took a mean of 39 day for resolution of their symptoms without intervention (132). Persons with horizontal canal (HC) BPPV had resolution of their symptoms within 16 days ± 19 without intervention. Imai et al. (132) also reported that more than 50% of their patients within 3 days of onset of the BPPV had a hospital ER visit associated with their symptoms, suggesting that having BPPV had a significant cost to the medical system.

There was good evidence in a recent systematic review that the Epley maneuver is effective at resolving vertigo associated with BPPV (133). In a sham versus CRM study, the CRM was more effective than the sham treatment (134). Others have suggested in a systematic review and a meta-analysis that BPPV improved with the CRM (33,135). In other randomized trials, the CRM was effective at eliminating the vertigo/dizziness associated with a change of position when compared to a control group (22,136,137).

It appears that HC BPPV may resolve spontaneously more quickly than posterior canal BPPV in a group of persons with relatively acute BPPV (1,132,138). They also noted little difference between those treated with the Lempert maneuver for HC BPPV versus those who were not treated for HC BPPV (138). HC BPPV is under 10% of the presenting cases of BPPV (68) and can occur as debris moves from the posterior canal into either the horizontal or anterior canal while performing the Epley maneuver for the posterior canal (139). Patients are highly symptomatic if the debris moves from the posterior to the HC during a repositioning with significant nystagmus and nausea reported with the canal conversion. If the debris moves from the posterior to the HC, we often finish the repositioning maneuver and attempt to have the patient return to the office the next day or within a few days, especially if they are older. They are usually too symptomatic to attempt to reposition again during the session. Generally, upon return to the clinic, the HC BPPV has resolved. Reassessment to determine if the patient has either posterior or HC BPPV is necessary in order to determine what intervention will be most efficacious.

There were significant differences in patient complaints in those treated with the modified Epley versus those who were untreated for posterior canal BPPV (138). Asawavichianginda et al. (140) reported that 84% of people with a positive Dix-Hallpike test were asymptomatic without intervention at 3 months, yet there are some patients with coexisting migraine or psychiatric disorders who continue to have psychiatric symptoms from the vestibular disorder 1 year after onset (141). Even those treated for BPPV successfully may have remaining dizziness symptoms, possibly because they have comorbid vestibular pathology (142). Those patients with remaining dizziness and balance dysfunction after the CRM who have a negative Dix-Hallpike maneuver often benefit from physical therapy intervention.

White et al. (124) reported in a systematic review that repositioning maneuvers are effective and improve quality of life, especially in older adults who experience BPPV. Immediately following repositioning therapy, many patients had resolution of disrupted perceptions of subjective visual vertigo (143) and improvement in their gait speed (125). These improvements suggest that the CRM changes a person's perception of "earth vertical" and their gait. However, persons with BPPV, especially older adults, may have disruption in their postural control system after repositioning and need a "tune up" of their balance before they are truly back to their baseline status, which may take a few days up to a few months post repositioning (10).

A recent publication suggests that after the CRM there were less reported falls 12 months post repositioning (144). Overall, the CRM performed by either the physician or the physical therapist appears to improve quality of life, decrease or eliminate dizziness, improve postural stability and gait, plus decrease the number of reported falls. Even for the physician who is very comfortable diagnosing and treating BPPV, there are certain situations in which the involvement of a vestibular physical therapist can be quite helpful. These would include persons with bilateral BPPV, morbid obesity, significant kyphosis or severe restrictions of motion in the neck, and recalcitrant BPPV with need for very frequent repositioning. While some studies suggest that CRM is equally successful in older persons (145), other studies point to a lower improvement rate in older persons and suggest that a combination of CRM and vestibular rehabilitation may improve outcome in older persons with BPPV (146).

Many patients, after repositioning, experience changes in their postural control (10). Recent evidence suggests that gait changes immediately after repositioning, yet older adults may complain of postural deficits up to 3 months post repositioning (10). A follow-up with a physical therapist is advised to ensure that the CRM was effective and that the person's balance has improved enough that the person is not at risk for falling.

Vestibular Neuritis

Exercises that promote VOR adaptation, substitution, and/or habituation are used to facilitate recovery of the VOR in persons with vestibular dysfunction (78,147–153). It is believed that eye/head movements with a focused target creates an error signal that allows the CNS to adapt resulting in less dizziness (152). Saccadic corrections are also made to minimize the error signal (147). Habituation, whereby patients are asked to move into and out of situations that provoke their symptoms, is also utilized (153). In addition, balance, flexibility, gait exercises, patient education, plus eye/head movements as noted above are performed as part of the therapy program (15,67,78). Most patients are seen one to two times per week initially (67). Persons with central vestibular disorders appear to take longer to recover (67). Total recovery for either peripheral or central vestibular pathology is unlikely, as Bowman has reported that even well compensated persons with unilateral peripheral vestibular dysfunction continue to have some functional deficits (118).

Strupp and Brandt (83) have suggested that persons with vestibular neuritis can develop persistent postural vertigo resulting in avoidance behavior. Avoiding movement most likely slows the rehabilitative process in humans. In the baboon animal model, Lacour et al. (154) have suggested that lack of movement can inhibit vestibular compensation. In older adults, avoiding movement could create additional functional limitations beyond those associated with the original vestibular deficit. Patients who are afraid to move because it makes them dizzy may develop neck stiffness and pain, decreased physical endurance, and decreased quality of life as a result of their self-imposed sedentary lifestyle. In a randomized trial, Strupp et al. (62) reported significant differences in postural control in those enrolled in a vestibular rehabilitation program compared to a control group (66).

In a recent randomized trial in 40 persons with an acute vestibular neuritis with a positive head thrust test and third degree nystagmus on admission, Teggi et al. (73) reported that early vestibular exercises resulted in better DHI scores, less anxiety, less reliance on visual cues, and better DGI. The exercise group means DHI, anxiety, and DGI scores were all "better" than the control subjects group outcome means at 25 days post onset of the exercise program. Early rehabilitation may help to decrease secondary complication such as fear of falling, neck stiffness, and anxiety about experiencing dizziness with movement.

Meniere Disease

Persons undergoing medical management for Meniere disease who complain of being unsteady between vertiginous attacks appear to benefit from vestibular physical therapy (31). It is more difficult to treat fluctuating disorders, yet postural control can be enhanced with an exercise program. Patients undergoing surgical or chemical (intratympanic gentamicin) ablation of vestibular function for Meniere disease can also benefit from early vestibular physical therapy (13,48).

Bilateral Vestibular Hypofunction

Bilateral vestibular hypofunction is often extremely disabling (12,25,43,64). While some affected persons can derive significant benefit from vestibular physical therapy, in others improvement may be limited. Gillespie and Minor (155) studied 35 patients with bilateral vestibular hypofunction who underwent vestibular physical therapy. Improvement was noted in 18 patients (51%) and 12 (34%) showed little or no change (155). Similar findings have been reported by others (12,43). Patients are often able to be taught to stand on uneven surfaces but continue to have difficulty in low or no light conditions. Patients with bilateral vestibular loss may require the use of an assistive device such as a cane or rolling walker to stabilize their gait (12,78). Those patients with total bilateral vestibular loss will continue to have complaints of oscillopsia with head movement and fall frequently (95). New technologies such as vibrotactile stimulation (156,157) and vestibular implants (158–161). (see Innovations section below) are expected to open new avenues of treatment for this challenging disorder.

Overall, changes in dizziness, balance, gait, and quality of life have been documented post vestibular rehabilitation in persons with peripheral vestibular disorders. Table 168.1 provides a summary of vestibular rehabilitation studies with peripheral and central diagnoses reported in the literature plus subjective and objective outcomes from the vestibular rehabilitation interventions.

CENTRAL VESTIBULAR DISORDERS

In a prospective, randomized controlled trial (n = 53), an early customized vestibular rehabilitation exercise program in older adults (age greater than 50 years) post acoustic neuroma resection was more effective at enhancing postural control at 3 months and was maintained at 1 year compared with those who were provided general instructions. A new concept in the literature is "PREHAB," whereby Magnusson et al. (48) have suggested that they are able to get people back to work faster by initiating rehab exercises *before* vestibular ablation (179). The "PREHAB" program was first implemented in subjects undergoing gentamicin treatments for Meniere disease and then adapted for use in patients with vestibular schwannomas with residual vestibular function. The latter patients were pretreated with gentamicin and vestibular exercises prior to undergoing translabyrinthine resection of cerebellopontine-angle tumors (48,179). Separating the vestibular ablation temporally from surgical resection allowed time for vestibular compensation

TABLE 168.1 COMMON VESTIBULAR DIAGNOSIS AND OBJECTIVE/SUBJECTIVE IMPROVEMENTS THAT HAVE BEEN REPORTED IN THE LITERATURE

Patient Diagnosis	Noted Improvement with Vestibular Physical Therapy
BPPV[a]	Subjective report of vertigo (16,54,134,146,162–164), nystagmus (16,146), quality of life (162)
Unilateral vestibular disorders	Fall risk (32,109), vision (32,37,64) balance (165,166), quality of life (52)
Chronic peripheral vestibular dysfunction	VOR gain and dizziness (14,167), standing balance (28,52,168), emotional status (i.e., anxiety) (169)
Bilateral vestibular dysfunction	Postural control (7,12,43), gait speed (12,43), dizziness (7,12,43), vision (36)
Vestibular neuritis	Ocular torsion (i.e., nystagmus (62)), postural control (35,62), ambulation skills and gait (15)
Post-acoustic neuroma resection	Postural control (35,170,171), dizziness (172), motion sensitivity (35)
Meniere disease	Self-report of symptoms (31), Balance (31), Dizziness, motion sensitivity (53)
Anxiety associated with vestibular disorder	Anxiety (173), subjective report (40), postural control (163), presence of nystagmus and ability to cope with dizziness (174)
Cervical vertigo	Postural stability (42), decreased neck pain (175), intensity of dizziness (42,175), postural sway (42)
Head injury	Gait improved (29), postural stability (29,63), less dizziness (34), gaze stability (30)
Cerebellar disease and dysfunction	Self perception of symptoms (25,26), postural control (25,26), gait (25), decreased risk of falling (25,26)
Multiple sclerosis	Subjective report of dizziness and postural control (176,177)
Parkinson's disease	Subjective complaint of vertigo (178)

[a]Medline search on July 27, 2010 revealed 512 papers on the search word "BPPV." Search was limited to randomized controlled trials in the past 10 years for the same search word and 17 papers were identified. Afterward, only relevant papers were chosen. Used with permission: Airwaily M, Whitney SL. Vestibular rehabilitation of older adults with dizziness. *Otolaryngol Clin North Am* 2011;44(2):473–496.

preoperatively leading to more rapid recovery (48,179). In a different surgical study, Cohen et al. (17) found that early postoperative vestibular rehabilitation did not affect vestibular compensation following acoustic neuroma surgery.

Persons with traumatic brain injury with vestibular dysfunction appear to benefit from a vestibular rehabilitation program (173). Persons demonstrated improvements in postural control, vertigo, and anxiety symptoms plus decrease in their perceived handicap. There is recent evidence to suggest that vestibular physical therapy may be effective in persons post concussion, who complain of balance or dizziness regardless of age (6). Vestibular rehabilitation also appears to be effective in persons with migraine dizziness (120,121), stroke (180), and even in persons with cerebellar disorders (26,180).

On many occasions, otolaryngologists evaluate dizzy persons with normal central and peripheral vestibular function based on the exam and/or vestibular testing or with vestibular pathology that does not have a medical treatment, that is, disequilibrium of aging, nonspecific dizziness. It is important to recall that even in the absence of objective vestibular pathology, vestibular physical therapy and, particularly, enrollment in an exercise program, has been demonstrated to decrease symptoms and, importantly, fall risk in dizzy persons (117,181). Regardless of whether objective vestibular pathology is identified, persons with a history of muscle weakness, previous falls, gait or balance deficit, or use of assistive devices should be referred for fall risk assessment and enrolled in an exercise program (181).

INNOVATIONS IN VESTIBULAR REHABILITATION

New advances in vestibular rehabilitation include the use of vibrotactile feedback, an implantable vestibular prosthesis, and the use of virtual reality to augment recovery after a vestibular deficit. Vibrotactile feedback was designed as a prosthetic device to assist with postural control (156,157,182–186) as a result of vestibular loss, injury, or aging. The devices currently in use typically "vibrate" the person's trunk (similar to the vibration that is typically felt from a cell phone) when they have exceeded some preset limit of stability (Fig. 168.1). The prosthesis has been shown to enhance postural control during standing and some preliminary works suggests that there are improvements during gait (157,183). Persons with unilateral vestibular disorders appear to be able to process the information and demonstrated greater accuracy of stepping and reduced trunk tilt with the device on (182). More study is required to determine if this type of technology can be used during gait and out in the community. Wall et al. (157) has suggested that vibrotactile feedback may assist in falls prevention for older adults, especially for persons with bilateral vestibular dysfunction who are at greater risk for a fall.

The development and implementation of an implantable vestibular prosthesis is moving forward and will have significant implications if they are as effective as the cochlear implant. Several centers around the world are working on the technology to provide a vestibular signal to persons with vestibular dysfunction (159–161). The

Figure 168.1 The vibrotactile device designed by Wall to provide feedback to persons lacking adequate vestibular inputs. Picture courtesy of Conrad Wall, PhD.

Hopkins Multichannel Vestibular Prosthesis (159) relies on three gyroscopes that are oriented orthogonally to capture head motion in the yaw, pitch, and roll planes. A microprocessor sends signals from the gyroscopes to electrodes implanted in the appropriate semicircular canals allowing stimulation of the ampullary nerves. Externally implanted devices have been tested in animal models with bilateral vestibular hypofunction and show promising results in terms of restoration of the VOR while preserving hearing (159,158). Challenges that remain in implementing this technology include miniaturization of the gyroscopes, enhancing the battery life and controlling current leak that leads to unwanted stimulation of adjacent ampullary nerves (159).

Recent evidence suggests that persons with vestibular disorders often complain of symptoms when there is high visual contrast and motion in the periphery (58,187). This motion-provoked dizziness phenomena has been called visual vertigo, space and motion discomfort, and also chronic subjective dizziness by various authors (188–190). Motion provoked symptoms are often seen in persons with a history of migraine and may be associated with persons who have anxiety or panic disorder (123,191–193). Staab et al. (194,195) have reported that selective serotonin reuptake inhibitors (SSRIs) were more effective in this patient population than benzodiazepines or vestibular suppressants. It is very difficult and sometimes impossible to treat persons with space and motion discomfort without medication. They complain of having difficulty walking in certain stores, in buildings with high ceilings and walls, in large open areas, or when challenged by movement in the periphery of their vision. These environments often escalate their symptoms, and over time, because of their increased symptoms, they avoid situations that promote their dizziness. Recent evidence suggests that some patients with uncompensated vestibular disorders with chronic subjective dizziness are more difficult to treat (190). It appears that vestibular rehabilitation in combination with pharmacologic management of their motion-provoked symptoms is optimal for management (190).

There are several physical therapy treatment interventions that have been designed to attempt to address these space and motion symptoms including exposure to more compelling visual scenes (58,59), virtual reality (196–205), and even the use of a disco ball to habituate and reprogram the CNS to be able to appropriately dose the exposure without an increase in dizziness and/or anxiety. Although physical therapists are not psychotherapists, there are components of their intervention programs that are very similar to psychotherapy that are used with patients with vestibular dysfunction.

Exposure therapy is one example of a treatment intervention that is shared between the two professions. Shopping in malls and grocery stores is an example of an activity that is very difficult for many patients with space and motion symptoms—it is unclear what factors within this environment increase the patients symptoms but it often is a subjective complaint in this subset of persons with chronic uncompensated vestibular disorders (187,198). Physical therapists will often ask patients to go to the edge of a shopping mall or to push a grocery cart within a store and over time will ask them to spend more time in the provocative environment. Eventually the patient is asked to move their heads and to move into more difficult areas of the store or mall as they improve with the goal of being able to move freely about the provocative environment without symptoms.

Virtual shopping environments have been designed in order to slowly progress patients exposure to habituate the patient to the environment that provokes the symptoms (Fig. 168.2) (196,199,206). Often patients learn to avoid the situations, thereby stopping all exposure to the symptom-inducing environments. There are some patients with uncompensated vestibular disorders, that when asked, will report that they are unable to enter a grocery store or large box stores where the ceilings are very high. Virtual environments and provocative scenes may promote habituation to the symptom-provoking scenes and over time decrease their symptoms. Pavlou et al. (58) have attempted to promote symptom reduction through visually provocative scenes as part of a home exercise regimen and also with

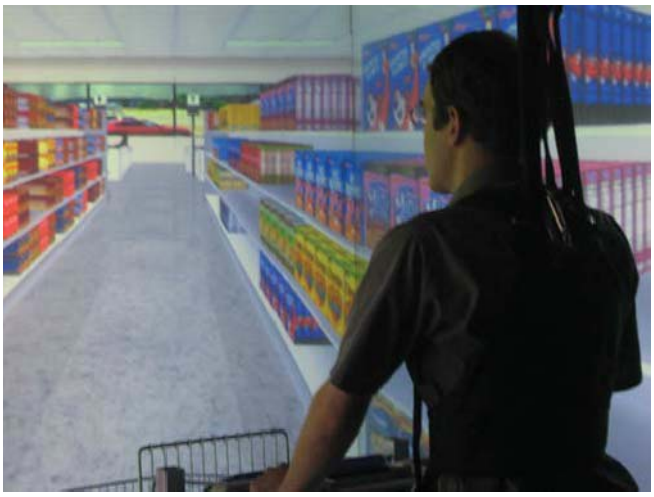

Figure 168.2 The person is ambulating in a virtual grocery store, which provides habituation of the response to the visual stimuli that increase the symptoms after a vestibular disorder.

a program where they attend sessions in the clinic and perform the exercises under the supervision of a physical therapist. The investigators have noted that even motivated persons do not comply well with a home exercise program without supervision and that patients must be slowly progressed with more provocative scenes in order for them to improve.

As with all aspects of exercises with patients with vestibular disorders, the physical therapist must carefully monitor the increase in symptoms that the exercises induce. If the patient becomes too symptomatic, the following can occur: they can become incapacitated from the symptoms and will stop exercising, they may become ill, or they become fearful of becoming ill again and limit their activity. Careful regulation of the "dose" of the exercise is required for optimal compliance and also for optimal recovery. Tool little movement may do little to nothing for the patients' recovery and too much eye/head movement may be detrimental for their well-being and recovery. If the exercise dose or exposure is too much, some patients may refuse further care or their anxiety may be increased, neither of which are good alternatives for the person with a vestibular disorder.

Working Together to Enhance Care

Patients with vestibular disorders need both good medical and physical therapy care. Working together as a team is the ideal situation for the patient, physician and physical therapist. It is not uncommon for patients to present to the physical therapist for dizziness even before seeing the physician as many physical therapists have been trained to triage for serious vestibular disorders. Developing a good working relationship can assist referrals going both ways-from the physician to the physical therapist and from the physical therapist to the physician for testing, diagnosis, and medical management. A good relationship can assist the physician in better understanding if the medication prescribed is effective via the frequent progress reports from other team members. In addition, the physical therapist may suggest to the physician that medication might be in order for the vestibular exercises to be effective. If a patient becomes too symptomatic performing exercises, rehab will have little effect on the eye/head movement symptoms without some type of symptom control with medication.

Persons with migraine or anxiety are particularly prone to needing medication for symptom control in order to get them to move more normally after a vestibular disorder (70,194,195). Those with migraine and anxiety appear to have a tendency to move less in order to minimize their symptoms. Persons with migraine-related dizziness may also have associated depression and panic disorder, with a higher prevalence in women than men and a poorer quality of life (207–209). Through communication with the treating therapist, medication prescription and adjustment often optimizes care.

Making decisions about return to driving is also often a shared task with the treating therapist, since the physical therapist is very familiar with the patient's functional capabilities. Driving is a concern to persons with vestibular disorders, as in many societies not driving is associated with significant social isolation and severe economic consequences. Sindwani et al. (210) reported that in persons with vestibular disorders who were warned not to drive by their physician, 44% stopped driving, 52% drove more carefully and 4% drove as they usually did. Vestibular disorders do affect some person's ability to drive, especially those with uncontrolled Meniere disease. Cohen et al. (211) have reported that patients with vestibular disorders while driving report difficulty with freeways, during a rain storm (most likely from the movement of the windshield wipers), in high traffic areas, with parking, with changing lanes, and with staying in a lane while driving. If the physician is in doubt, a driver's examination may be in order. Certain physical therapists (Driving Rehabilitation specialists) can assess the appropriate automobile driving skills and safety in those with complaints of constant or intermittent dizziness. Large rehabilitation centers often have driving simulators that can assist you in determining if it is safe for the patient to be driving.

Return to work after a vestibular disorder is often one of the most difficult decisions to make as a physician. There are no clear cut criteria for return to work for the person with dizziness. The physical therapist can help with the decision about return to work. Careful consideration should be made for the following work situations: working around hazardous situations/machines, working alone, working at heights, working in deep water, working in environments that move, and when the safety of others is at risk (212). Job categories that might require special consideration include the armed forces, construction work,

factory jobs that require repetitive head movement, police and fire work, long and short distance hauling of materials/driving, pilots, and working on sea or river vessels.

In summary, vestibular rehabilitation has been demonstrated to be effective in assisting in the recovery of persons with dizziness and balance disorders. A close working relationship between the physician and physical therapist facilitates expedient and effective patient care.

HIGHLIGHTS

- Vestibular rehabilitation is an effective intervention for persons with peripheral vestibular disorders.
- Early referral for persons with peripheral vestibular disorders is optimal resulting in enhanced quality of life.
- For vestibular hypofunction, anti dizziness medication may slow vestibular compensation.
- Customized exercise programs appear to be superior to a generic exercise program.
- Regardless of age, function can improve in patients with dizziness who actively participate in a program of vestibular rehabilitation.
- A tailored exercise program delivered both at home and in the clinic facilitates recovery and reduces falls.

Regenerative Strategies for Overcoming Deafness

169

Alan G. Cheng *Stefan Heller*

The mammalian organ of Corti comprises a complex but organized array of mechanosensitive hair cells separated by supporting cells (see Fig. 169.1). Upon mechanical stimulation, inner hair cells transmit neural signals to innervating spiral ganglia neurons, which in turn relay neural impulses to the central nervous system in a tonopic manner. Simultaneously, outer hair cells feed back mechanical forces to augment the sensitivity and frequency selectivity of the cochlea. The integrity of all of these cell types is critical for auditory function.

Etiologies of hearing loss include genetic disorders, acoustic trauma, aging, infection, and toxins such as aminoglycoside antibiotics and the antineoplastic agent cisplatin. One common underlying pathology of hearing loss is degeneration of outer and/or inner hair cells. While hair cell–specific mutations, certain drugs (e.g., aminoglycosides and cisplatin) and noise are likely the primary cause for sensory hair cell loss, there are also scenarios in which hair cells degenerate in non–cell autonomous fashion. Such a pattern of cell loss has also been observed in lesions primarily involving the supporting cells such as gap junction gene mutations (e.g., *GJB2* encoding connexin 26) (1) or mutations that affect ion homeostasis in the stria vascularis (2). Because of the established causal relationship between hair cell loss and hearing loss, much effort has been devoted to investigate hair cell regeneration as a possible therapeutic intervention for hearing loss.

HAIR CELL REGENERATION, NONMAMMALIAN VERTEBRATES VERSUS MAMMALS

In non-mammalian vertebrates such as fish, amphibians, and birds, sensory organs have the inherent capacity to replace lost hair cells. In fish, the lateral line organs are used to detect water movement and contain hair cells that are continuously turned over and replaced (3). Likewise, in the vestibular organs in birds, sensory hair cells degenerate and regenerate at a steady state, and the degree of regeneration increases upon damage by aminoglycoside treatment, which has been investigated in the macula of utricle (4,5), suggesting that loss of hair cells induces a repair response. A similar regenerative response exists in the avian basilar papilla (hearing organ in birds), where researchers discovered recurrence of sensory hair cells initially lost from damage caused by aminoglycoside or noise (6–8). Indeed, these newly regenerated hair cells were innervated and hearing function was restored (9). Complex cortical functions including language acquisition requires intact neural connections between the cochlear end organ to higher cortical centers. When correlates of such learning ability were examined, song birds with regenerated cochleae that had initially been lesioned with aminoglycosides learnt and sang new songs (10). These lines of evidence indicate that in non-mammalian vertebrates, hair cell regeneration is part of the inner ear's natural self-repair process.

In recent years, researchers have built on the above initial findings to delineate the mechanisms underlying hair cell regeneration. Using thymidine analogs to mark proliferating cells, the supporting cells in both the avian basilar papilla and utricles were found to generate new hair cells in two manners: via mitotic division or transdifferentiation (11). Transdifferentiation occurs when supporting cells directly acquire a hair cell phenotype without a preceding mitotic division. When the process of hair cell regeneration was examined in the avian cochlea after lesioning by aminoglycosides, both processes significantly contribute to the repopulation of lost hair cells (11,12). Inhibitors of proliferation do not affect the degree of supporting cell transdifferentiation, suggesting that the two mechanisms may operate independently of each other (12).

In the mammalian cochlea, loss of hair cells is permanent and no spontaneous regeneration of hair cells has been observed. Unlike the cochlea, limited hair cell

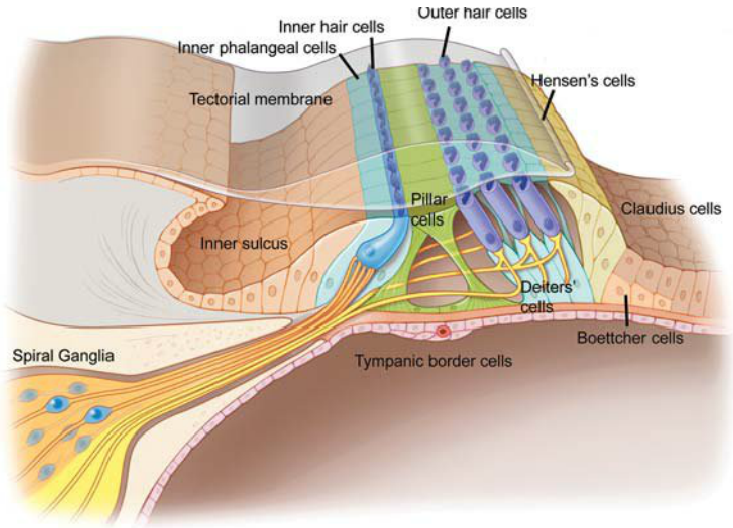

Figure 169.1 Anatomy of the mammalian organ of Corti. The hearing organ consists of three rows of outer hair cells and one row of inner hair cells. Six subtypes of supporting cells have been described (inner phalangeal, pillar, Deiters', Hensen's, Boettcher, and Claudius cells). Figure © Stanford University.

regeneration has been observed in mammalian utricles. Morphologic evidence suggests that new, immature hair cells appear after aminoglycoside damage *in vitro* (13,14), yet the lack of proliferation marker among these hair cells implies that they emerge via transdifferentiation, most likely from supporting cells. Recently, cells isolated from the mammalian utricular sensory epithelium were found to have stem cell properties, where they self-renew and were pluripotent (15), and may contribute to the regenerative capacity of utricles. Cells with stem cell properties were also found in the neonatal (see section below), but not adult cochlea (16); mechanisms underlying this fundamental difference between the mammalian auditory and balance organs are not completely understood.

In cochlea damaged as a result of aminoglycoside administration, hair cell loss is accompanied by an initial preservation of adjacent supporting cells (17). Although expression of specific markers in surviving supporting cells are mostly unaltered immediately after damage, the architecture of the sensory epithelium successively transforms from pseudostratified and complex, via an intermediate cell mound with collapsed tunnel of Corti, into to a flat, monolayered epithelium (see Fig. 169.2). A modest loss of supporting cells was noted in long deafened cochleae (17–19).

Aminoglycoside-induced hair cell loss is one of the best understood model systems for hearing loss/deafness. Studies on this model of cochlear degeneration illustrate the dynamic cellular and architectural changes following hair cell degeneration, and allow the investigation of various approaches aiming to regenerate hair cells. Yet it is important to note that this model of cochlear degeneration may differ, at least in part, from other causes of hearing loss such as those involving other cell types including mutations of the connexin or pendrin genes (1,20).

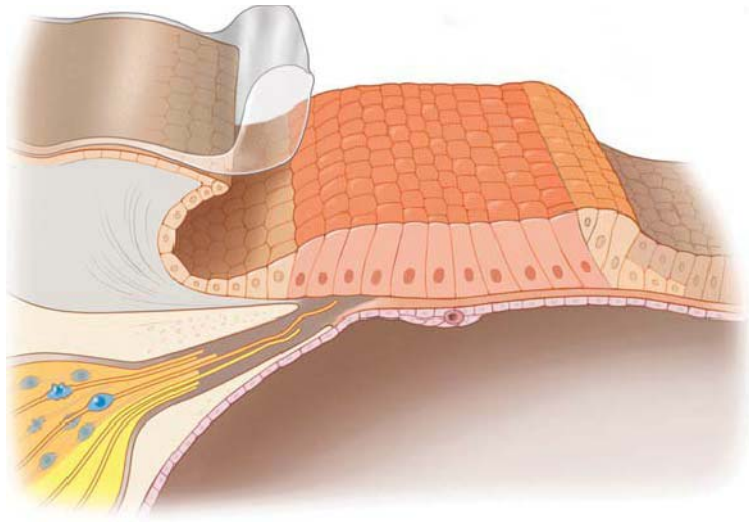

Figure 169.2 Degenerated mammalian organ of Corti. After extensive hair cell loss, the epithelial integrity is maintained by the remaining supporting cells, which morphologically transform from a complex and pseudostratified organ into a mostly simple cuboidal epithelium. Figure © Stanford University.

NOTCH PATHWAY

One key molecular pathway regulating hair cell differentiation is the Notch signaling pathway, which plays several roles during the development of many organ systems. In regenerating chicken basilar papilla, Notch ligand expression is upregulated and inhibition of Notch signaling causes excessive regeneration of hair cells (21). This finding suggests that active Notch signaling functions to suppress supporting cells from acquiring a hair cell fate. However, Notch inhibition fails to induce extra hair cell formation from quiescent supporting cells in the undamaged avian cochlea, suggesting that a separate damage-induced signal is necessary.

In the developing cochlear duct, hair cells and supporting cells share a common progenitor (22). During late embryogenesis, Notch signaling pathway regulates the mammalian cochlea through a process termed lateral inhibition (reviewed in [23]). Developing hair cells express Notch ligands (24,25), which in turn activate Notch signaling in adjacent supporting cells. Active Notch signaling in supporting cells turns on the *Hes* and *Hey* genes and represses the expression of *Atoh1*, a gene critical for hair cell differentiation (see section below). Such an interaction is important in the formation of rows of hair cells intercalated by supporting cells (26). Similar to the avian cochlea, inhibition of the Notch pathway leads to ectopic hair cell formation in the embryonic and early postnatal mouse cochlea, indicating that mammalian supporting cells have the potential to acquire a hair cell phenotype (27–30). Stringent analyses identified a subset of organ of Corti supporting cells capable of directly differentiating into hair cells in the neonatal mouse cochlea: (a) inhibition of Notch signaling leads to excessive outer hair cells at the expense of Deiters' cells, and (b) inhibition of both Notch and fibroblast growth factor (FGF) signaling causes formation of excessive inner hair cells from pillar cells (29,31). Together these experiments suggest that supporting cells can be coerced to become new hair cells, and raise the question whether they can also function to replace lost hair cells under pathologic conditions.

To gain insights into the role of Notch signaling in hair cell regeneration, researchers have studied the use of gamma secretase inhibitors, which are potent antagonists of Notch signaling by preventing cleavage and release of the intracellular domain on Notch receptors that is responsible for downstream gene regulation. In damaged chicken basilar papilla and the zebrafish lateral line system, both organs that spontaneously regenerate lost hair cells, Notch inhibition led to an increase in hair cell production (21,32). These observations suggest that events occurring during hair cell regeneration recapitulate those in development.

Whether inhibition of Notch signaling can stimulate hair cell regeneration in the mature mammalian cochlea has not been extensively examined. In one study where guinea pigs were deafened by aminoglycoside, pharmacologic inhibition of Notch signaling has yielded limited ectopic hair cells without regeneration of outer or inner hair cells (33). Though discouraging, these results suggest that supporting cells in the mature organ of Corti have lost responsiveness to Notch inhibition. However, mechanisms underlying this loss of competence are currently unknown and warrant further investigation.

ATOH1 GENE THERAPY

The basic helix-loop-helix transcription factor Atoh1 (also known as Math1) is one of the earliest markers for hair cell differentiation (34). In mutant mice lacking *Atoh1*, hair cells fail to develop, indicating that the gene is necessary for their genesis (35,36). To investigate whether *Atoh1* is sufficient to induce hair cell formation, several groups have examined the effects of *Atoh1* overexpression in the developing and mature cochlea. When introduced in the developing otocyst *in utero*, cells transfected with *Atoh1* generated ectopic hair cells that are innervated and demonstrated mechanosensitivity, both cardinal features of functional hair cells (37). When *Atoh1*-expressing plasmids were administered to mammalian cochlear explants, independent studies have found ectopic hair cells in the greater epithelial ridge adjacent to the organ of Corti (36,38). These data suggest that defined cell populations in the embryonic and early postnatal cochlea can generate new hair cells when coerced to express *Atoh1*. Of note, new supporting cells are formed adjacent to the newly formed hair cells, likely as a result of inductive signals originating from these new hair cells (36).

Using adenovirus vehicle to force express *Atoh1*, Kawamoto et al. (39) found that limited nonsensory cells remain competent to be induced to form ectopic hair cells in the mature cochlea in guinea pigs. In a follow-up study, Izumikawa et al. (40) applied this intervention to the adult guinea pig cochleae 4 days following deafening by aminoglycoside insults, and reported hair cell regeneration and subsequent improved auditory brainstem thresholds. However, no hair cell regeneration or functional recovery was observed when the *Atoh1* gene was delivered 1 week after deafening from aminoglycoside/diuretic treatment, when the sensory epithelium was severely degenerated and on course to form a flat epithelium. While these results suggest that introducing genes important for hair cell differentiation, such as *Atoh1*, may hold promise as an intervention for deafness, the mixed outcomes of studies and the limited time window of opportunity, however, warrant further investigation to better understand this approach for future treatment.

CELL CYCLE INHIBITION

The postnatal mammalian organ of Corti is postmitotic. Studies using thymidine analog uptake have indicated that cells of the mammalian organ of Corti have gone

through the last phase of mitosis between embryonic day 12.5 to 16 (41,42). Several cell cycle regulators are upregulated during this period and are thought to be important to transition the proliferative prosensory region to differentiated organ of Corti. $p27^{Kip1}$, a member of the cyclin-dependent kinase inhibitors, is expressed in the prosensory region (where hair cells first emerge) of the developing cochlea and becomes restricted to supporting cells in the postnatal organ of Corti (42,43). Deficiency of $p27^{Kip1}$ leads to both increased and prolonged proliferation in the cochlea, as well as supernumerary hair cells (43,44). These mutant mice with extra hair cells have significant hearing loss and their cochleae exhibit distorted cytoarchitecture. When one of the downstream targets of cyclin-dependent kinase inhibitors, the retinoblastoma protein, is deleted (45,46), ongoing proliferation of supporting cells and hair cells were observed in the late embryonic and postnatal ages, indicating that retinoblastoma is also required for cell cycle exit in the developing cochlea. Although these overproduced hair cells are mechanosensitive, a delayed degeneration and hearing loss were observed (45–47). These results highlight two major challenges underlying hair cell regeneration: (a) preserving the intricate cellular organization and cell number in the organ of Corti is critical for its function; (b) signals inducing hair cell regeneration are probably different from those maintaining hair cell integrity. To add to this complexity, acute ablation of retinoblastoma expression fails to induce proliferation or hair cell regeneration in the adult cochlea (48), suggesting that manipulating the cell cycle pathway alone is not sufficient to awaken the mitotically quiescent cells, but the effectiveness of this approach has not been fully investigated in the damaged organ. Although supporting cells in the mature avian cochlea are likewise quiescent at rest, they are capable of reentering a proliferative state and regenerating lost hair cells as a result of noise or aminoglycoside damage. Studies on the effects of hair cell damage on the cell cycle in supporting cells are scarce, and existing evidence suggests a low level of proliferation exists as a result of hair cell loss in the mature mammalian cochlea (49). At present, our understanding of how cell cycle is regulated in the normal and damaged adult mammalian cochlea is limited and advancing it will likely be a necessary step toward inner ear regeneration.

SOMATIC STEM CELLS

In the developing cochlear duct, sensory hair cells and nonsensory supporting cells derive from common progenitor cells. During regeneration in the avian cochlea, experiments using label retention assays demonstrated that supporting cells are the source of regenerated hair cells (6–8). They behave as stem cells because they divide asymmetrically and self-renew by generating additional supporting cells, while also giving birth to daughter cells that differentiate into *bona fide* hair cells. The mammalian cochlea, unlike its avian counterpart, does not contain supporting cells that readily proliferate upon hair cell loss nor do they spontaneously regenerate hair cells. However, recent evidence shows that the mammalian cochlea harbors cells with regenerative capacity in the early postnatal period (16,50–55).

Using a cell-based assay established to study neural stem cells, investigators have found that both the mature vestibular system and the neonatal cochlea in mice contain stem cell-like cells (15,16). They behave as stem cells in that they self-renew and also differentiate into hair cell– and supporting cell–like cells *in vitro* and upon transplantation. Recent work suggests that several cell populations in the neonatal mouse cochlea have differential potentials to proliferate and produce new hair cells (54). However, this regenerative capacity rapidly decreases during the first 3 weeks of life (16); the mechanisms underlying this loss are currently unknown. It remains to be determined whether one can rekindle these endogenous stem/progenitor cells from the developing cochlea to repair a damaged adult cochlea.

Unlike the cochlea, several mammalian organ systems continue to self-renew throughout life. These systems include the skin, hematopoietic, and intestinal organs, which contain well-characterized endogenous stem cells. While there have been several attempts at transplanting such stem cells as well as embryonic stem cells (see next section) into a damaged cochlea, results have been mixed on the success rates of cell survival, integration, and functional improvement (56–60).

EMBRYONIC STEM CELLS AND INDUCED PLURIPOTENT STEM CELLS

Embryonic stem cells originate from the inner cell mass during fetal development. They are able to self-renew and generate all cell types within the body, and are therefore an attractive resource for tissue regeneration. Induced pluripotent stem cells are similar to embryonic stem cells: they self-renew and are pluripotent. By introducing defined factors, many laboratories have reliably generated induced pluripotent stem cells from mature tissues, such as skin fibroblasts (reviewed by [61]). Several years ago, Li et al. (62) described a first protocol that guided differentiation of mouse embryonic stem cells into otic progenitor cells, which when transplanted into developing chicken otocyst, differentiated into hair cell–like cells. In a follow up study, Oshima et al. (63) refined this differentiation guidance method for both mouse embryonic stem cells and induced pluripotent stem cells so that new mechanosensitive hair cells were produced *in vitro*.

While these proofs of principle experiments have yielded encouraging results, it is unknown whether transplanting otic progenitors or more mature cochlear cell types into a deafened cochlea can regenerate hair cells and auditory function. Thus far, results on integration of transplanted otic progenitor cells derived from embryonic stem cells, like those of adult stem cells, have been mixed (see

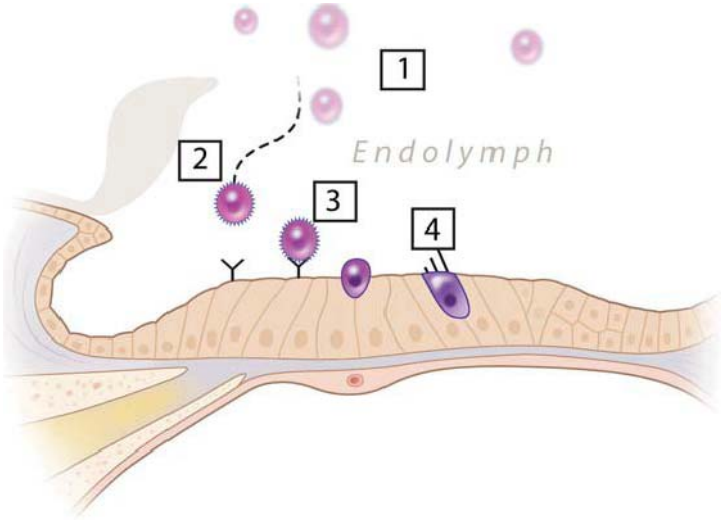

Figure 169.3 Schematic of stem cell transplantation into the inner ear. Grafting into the scala media compartment is one of several approaches to introducing cells into the inner ear. Transplanted cells will first need to survive in the endolymph fluid (*1*), then integrate into the sensory epithelium (*2–3*), and ultimately convert into functional sensory hair cells (*3*). Figure © Stanford University.

Fig. 169.3) (64–66). While some studies have reported functional recovery of deafened animals, others have observed poor survival of grafted cells and even the formation of tumors, likely teratomas. Collectively, these results highlight the challenges of cell-based therapy in treating inner ear diseases and are related to numerous factors (see Fig. 169.3): (a) the inner ear, especially the scala media housing the organ of Corti, is difficult to access for cell transplantation. Within the scala media, the electrolyte composition (high potassium) of endolymph is potentially inhospitable for grafted cells, (b) it is unclear what cell types are best suited to graft (undifferentiated stem cells, committed tissue-specific stem cells, or purified progenitor cells); (c) little is known about homing signals in the normal or damaged cochlea that may attract transplanted cells; (d) whether grafted cells will be integrated and become functional hair cells along the entire length of the cochlea is currently unclear. Without such knowledge, it is difficult to predict whether cell transplantation is a feasible route to functional recovery of the mammalian cochlea.

SUMMARY

Since the discovery of hair cell regeneration in lower vertebrates over 20 years ago, our understanding of the regenerative potentials of the mammalian cochlea has increased tremendously. In recent years, the armamentarium to investigate the mammalian cochlea has been rapidly growing and now consists of many molecular and cell-based approaches. Manipulation of the Notch and/or FGF pathways can recruit subsets of nonsensory supporting cells to generate extranumerary hair cells in the neonatal mouse cochlea, where forced expression of *Atoh1* can induce ectopic hair cell formation. Hair cells can also be produced from embryonic stem cells and induced pluripotent stem cells *in vitro*, yet many obstacles exists for cell transplantation into the inner ear. It is important to note that most studies on hair cell regeneration thus far have employed drug- or noise-induced hair cell degeneration as model systems; however, treatment paradigms will likely differ for other causes of hearing loss, such as genetic diseases, age-related hearing loss, or auditory dyssynchrony spectrum disorder. In the coming years, new discoveries will likely continue to transform our understanding of the regenerative capacity of the mammalian cochlea. Importantly, the long-term efficacy and safety of the newly discovered interventions will need to be carefully interrogated before they are translated to new approaches to managing patients with sensorineural hearing loss.

HIGHLIGHTS

- Hair cell degeneration occurs in many modes of sensorineural hearing loss.
- The mature mammalian organ of Corti lacks the ability to regenerate lost hair cells.
- The Notch signaling pathway mediates lateral inhibition and hair cell differentiation during cochlear development.
- The Atoh1 transcription factor is necessary and sufficient for hair cell differentiation.
- The neonatal mouse cochlea harbors cells with regenerative potential.
- Mouse embryonic and induced pluripotent stem cells can generate mechanosensitive hair cells *in vitro*.

Preoperative Evaluation and Facial Analysis in Facial Plastic Surgery

170

Andrew Winkler *Justin M. Wudel*

CONCEPT OF BEAUTY AND DEFORMITY

Western civilization portrays facial beauty as flawless, young skin with ideal facial contours. Youth and beauty are pervasive in all forms of media, highlighting their significance to our culture and to humans in general (1). The value that our society places on beauty has lead to innumerable methods of enhancing one's attractiveness, including cosmetic surgery. Today, the desire to change one's appearance is considered a sufficient indication for surgery, whether or not a true "deformity" is present. The continual growth in the number of cosmetic procedures performed each year reflects the public's rapidly growing acceptance of cosmetic surgery as a means of self-improvement.

The physician and patient usually share a perception of deformity and the correction needed. Some patients, however, perceive an abnormality not readily apparent to other people. A significant difference between the perceived deformity and the surgeon's assessment of the feature raises warning flags that may warrant further evaluation. This chapter aids in defining what does and does not constitute deformity and how to elucidate whether a patient's requests are within normal limits. Psychiatric conditions that may lead to a disagreement in facial assessment between patient and surgeon are also discussed. The absolute numeric values presented in this chapter allow the surgeon to determine whether or not a feature is proportionate. However, facial features must also form a harmonious union when observed together. Harmony refers to the mind's interpretation of the facial relationships based strictly on visual observation (2). For facial beauty to exist, the proportions and architecture of the face must form a balance that is visually pleasing. When the major aesthetic masses of the face (nose, lips, ears, eyes, etc.) are individually proportionate, they are more likely to harmonize with each other to yield an aesthetically pleasing facial appearance. However, disproportionate features may also harmonize with one another, even though the feature itself falls outside of what is considered normal. Consequently, beauty is to a degree in the eye of the beholder, and aesthetic facial analysis remains a partially subjective exercise.

INITIAL CONSULTATION

Establishing a Relationship

The primary goal of the preoperative interview is to establish effective communication in order to obtain an understanding the patient's perception of the defect, the patient's motivations, and the patient's expectations from surgery (3). During the interview, the patient's thoughts and feelings about the area of concern are explored. This provides an opportunity to educate the patient about the details of potential surgery and what outcomes may be realistically achieved. The preoperative interview is also an opportunity to a review the medical history to identify conditions that may preclude surgery. Spending time with potential medical issues improves trust and rapport and may reveal issues needing further evaluation prior to undergoing elective surgery. A surgeon's mastery of the relationship-building phase of the interview results in improved patient satisfaction, reduced legal liability, and better surgical outcomes (4,5).

Preoperative Assessment

A commonsense approach to selecting candidates for surgery greatly reduces the chance of encountering an unhappy patient (6). In the preoperative interview, the surgeon seeks answers to the following questions:

- What are the patient's expectations?
- Are the expectations realistic and reasonable?
- Do I have the ability to fulfill these expectations?
- Can the patient be satisfied?

TABLE 170.1 RED FLAG SYMPTOMS. PATIENTS EXHIBITING "RED FLAGS" MAY WARRANT FURTHER INVESTIGATION

Trying to please someone else
Unrealistic expectations
Pervasively unhappy
Poor self-image
Overly flattering
Perfectionists
Rude or demanding
Know-it-all
History of doctor-shopping
History of litigation
Multiple revision surgeries

Many tools are available to aid in obtaining this information. The Sensitization, Aesthetic self-assessment, peer Group comparison and Avoidance behaviors (SAGA) tool helps to uncover patients' understanding of normal, their perception of deformity, and its impact on them (7). Sensitization refers to the point at which the patient becomes aware of and bothered by a deformity. The impetus for sensitization may be self-induced (intrinsic) or the result of extraneous remarks or teasing (extrinsic). Alternatively, the patient may not be sensitized to a deformity and may be requesting surgery to please someone else, a red flag symptom (Table 170.1).

The second concept evaluated by the SAGA tool is aesthetic self-assessment. This is the patient's private evaluation of the concerning feature in a mirror. Simply inquiring about self-assessment builds rapport and reassures the patient that this is normal behavior. The self-assessment also gives an impression of the desired improvements and whether these expectations are realistic.

Peer group comparison gives insight into patient sensitization as well as their reaction to the deformity. A patient sensitized to a feature will scrutinize others in society (7). The patient desiring to appear like that of a particular movie star reveals unrealistic expectations, and such patients are likely to blame the surgeon for perceived poor results. The patients' ability to accept the surgical result is highly correlated with the degree to which they are prepared by their surgeon. Unrealistic expectations must be discussed prior to undergoing surgery (8).

Avoidance behaviors examine the techniques and strategies used by the patient to camouflage or conceal their imperfections. This may include makeup, clothing, or a hairstyle used to cover up or draw attention away from the featured complaint. Avoidance behaviors should resolve with surgery and may provide an objective measure of success postoperatively.

The experienced surgeon develops wariness for patients who create a sense of uneasiness. Situations that raise caution flags include a history of having sued another surgeon, extreme demands of support staff, or evidence of "doctor-shopping" in search of someone who will perform the desired surgery. Such patients should be approached with extreme care and often require further evaluation (Table 170.1).

PSYCHOPATHOLOGY IN THE AESTHETIC PATIENT

It was not long ago that patients seeking aesthetic surgery were assumed to have deeply seated psychological issues. In 1960, Jacobson et al. (9), suggested that most cosmetic surgery patients required psychological evaluation because psychiatric problems were almost certainly present. As cultural norms have evolved, the level of concern about physical appearance that was once deemed psychologically abnormal is now acceptable and it is rare for a patient to require preoperative psychiatric evaluation. The rate of psychopathology in cosmetic surgery patients today approaches that of the general population. Nevertheless, only a small percentage of the population actively seeks surgery despite a continual increase in popularity. This is due to personality characteristics that differentiate those who seek cosmetic surgery from those who do not (4,10). On the extreme end of the personality spectrum are patients with diagnosable psychiatric conditions. The following section describes important pathologic conditions to consider during the initial consultation.

Depression

Traditionally, patients carrying a diagnosis of depression were rejected for facial cosmetic surgery as it was feared this would trigger deeper depression (11). In a study from 1960, patients with late-onset and prolonged depression after cosmetic procedures exhibited a causal relation between surgery and depression. This group of patients received support in the immediate postoperative period that was initially satisfying. As the sought-after attention waned, however, the patients realized that surgery had not fulfilled their desires, and they became more depressed. While a diagnosis of depression is not a contraindication to surgery, there remains a risk of depression intensifying following surgery. We now know that almost half of aesthetic surgery patients display clinically apparent postoperative depression, even with a good outcome (11,12). Despite this finding, Moss and Harris (13) demonstrated a significant improvement in patient's postoperative Beck Depression Inventory score following cosmetic surgery in comparison to their preoperative scores. It is generally accepted that patients with a preoperative diagnosis of depression can undergo cosmetic surgery without fear of long-term intensification of their symptoms, although coordination between the surgeon and psychiatrist yields the best results.

Personality Disorder

Personality disorders are psychiatric conditions in which a person's behaviors, emotions, and thoughts are markedly different from that of their culture, causing serious problems with relationships and work. Personality disorders are the most common psychopathology seen in patients seeking cosmetic surgery (14). These patients are manipulative, demanding, and difficult to please. Of all personality disorders, narcissistic and histrionic personality disorders are most commonly encountered by facial plastic surgeons (15). Although the overall prevalence of narcissistic personality disorder in the general population is 1%, up to 25% of patients who present to a plastic surgery practice display hallmarks of the diagnosis, including unexplained grandiosity accompanied by a need for admiration (14,16). Similarly, although the incidence of histrionic personality disorder in the general population is 1.8%, up to 10% of cosmetic surgery patients have this condition, marked by attention-seeking behavior, excessive emotionality, and sexual forwardness (15,16). A third personality disorder to consider is borderline personality disorder (BPD). People with BPD are uncertain about their identity, and as a result their interests and values change rapidly. These patients perceive their environment in terms of extremes, leading to rapidly shifting feelings and unstable relationships (16). The encounter with a patient who has a personality disorder can be one of frustration and aggravation. Nevertheless, an appropriate doctor-patient relationship must be established. If the surgeon is not confident that this relationship can be maintained or the patient will not cooperate, surgery should not be performed.

Body Dysmorphic Disorder

One of the most difficult challenges facing a plastic surgeon occurs when there is disagreement with a patient regarding the degree of deformity. While it is not uncommon to encounter patients who would like to have minor deformities corrected or improved, it is important to recognize patients who fall outside of the normal spectrum. The extreme example of this is body dysmorphic disorder (BDD), a condition characterized by the unhealthy obsession with one or more body parts (16). Patients with BDD have a preoccupation with some slight or perceived flaw in their physical appearance. These individuals spend an excessive amount of time thinking about their personal appearance and methods to change it. BDD is estimated to occur in approximately 1% of the general population, but the incidence is up to 16 times higher in patients desiring plastic surgery (17). When a patient demonstrates profound emotional distress and behavioral impairment out of proportion to the actual defect, the plastic surgeon is wise to refer the patient for psychiatric evaluation. The mainstay of treatment for the behavioral components of BDD is cognitive behavior therapy (18). BDD is a somatoform disorder that cannot be effectively treated with surgery and therefore these patients are not surgical candidates. BDD patients are more likely to move to litigation, and may even threaten physical violence.

FACIAL ANALYSIS

History

The desire to identify ideal facial aesthetics dates to antiquity. Greek artists sought to identify ideal facial proportions and began to formally analyze beauty. The classical Greek canons of facial balance that were developed consequently influenced anatomic scholars of the Renaissance period, and many of these form the foundation of facial analysis today.

Ricketts (19) supported the Greek concept that facial attractiveness is related to the repetition of proportions throughout the face. The ideal or "divine" proportion equates to the mathematical ratio of 1:1.618 (phi), which was believed to be the rate of mathematical progression most pleasing to the eye. The ratio refers to the point along a line at which the ratio of the smaller portion to the larger portion is the same as the ratio of the larger portion to the original line (Fig. 170.1) (20).

Farkas et al. (21) performed detailed anthropometric studies of different ethnic populations to assess the validity of the classical Greek canons for beauty and determined multiple "normal" values for various facial proportions. Measurement and memorization of normal values is cumbersome and quickly becomes impractical for everyday use by aesthetic surgeons.

Modern science defines beauty as a biologic and cross-cultural concept of attractiveness. In one study (22), infants preferred looking at aesthetically pleasing adult faces. Other studies (23) note a preference for symmetry in facial architecture (24,25). Another (26) found that test subjects preferred a composite of attractive faces to a composite of average faces, which was consistent across ethnic boundaries. Ethnic differences in aesthetic ideals exist, however, and must be considered during facial analysis to avoid inappropriate "Westernization" of ethnic features (27–31).

Defining Terms

The face is a complex balance of multiple aesthetic units that when taken together produces a unique appearance. Facial analysis uses standardized points to determine

Figure 170.1 When the ratio of the long segment to the short segment (AB/BC) is the same as the ratio of the whole line to the long segment (AC/AB), the ratio is equivalent to the divine ratio, phi (1.618). (Adapted from Ricketts RM. Divine proportions in facial esthetics. *Clin Plast Surg* 1982;9:401–422, with permission.)

TABLE 170.2 BASIC ANATOMIC LANDMARKS AS SEEN ON FRONTAL VIEW

Trichion (Tn)	Superior margin of the forehead at the midline of the frontal hairline
Radix (R)	The region of the root of the nose
Subnasale (Sn)	Soft tissue point at the junction of the columella and upper lip in the midline
Superior and inferior vermilion border (Vs and Vi)	Mucocutaneous junction of the upper and lower lips
Stomion (St)	Midline point at the embrasure of the lips when closed
Menton (M)	Soft tissue point at the inferior-most border of the chin in the midline

relationships between various aesthetic masses, and to determine the proportions of each feature individually. The following tables define standard reference points used in facial analysis (Tables 170.1 and 170.2, Fig. 170.2). Using these standard points, reference angles are constructed to analyze interfacial relationships. These values serve as a general reference, but values vary from male to female and between ethnic groups. Men tend to have sharper angles and more prominent features than women. These differences help us subconsciously determine gender, as well as the degree of masculinity and femininity.

General Facial Assessment

Facial assessment begins with an evaluation of symmetry. A line drawn through the midsagittal plane on frontal view provides a side-by-side comparison of symmetry. The midline points of the forehead, nose, lips, and chin should lie on this axis. Subtle asymmetries are expected and it is helpful to point these out to the patient preoperatively.

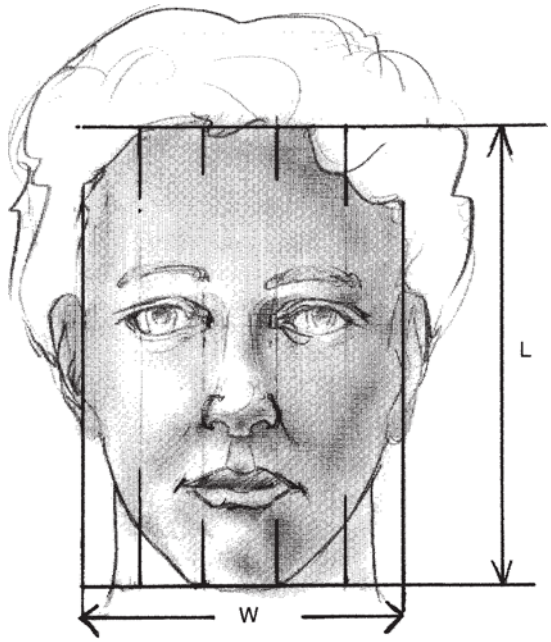

Figure 170.3 Ideal frontal symmetry and proportion is approximated by dividing the face into vertical fifths, with each fifth approximating the width of the eye. The overall width-to-length ratio should approximate 3:4.

Assessment of symmetry and proportion is further accomplished by dividing the face into vertical fifths equal to the width of one eye, or the intercanthal distance. Vertical lines at the lateral canthus should approximate the width of the neck (32). The lateral-most fifth extends from the lateral canthus to the lateral most point of the helical rim (Fig. 170.3).

Facial height is examined by dividing the face into horizontal thirds on the frontal and lateral views (Fig. 170.4). The total facial height is the distance from the trichion to the menton. However, the trichion can be an inaccurate landmark due to receding hairlines in some individuals. In these cases the trichion is approximated by marking the uppermost extent of frontalis movement. The face is

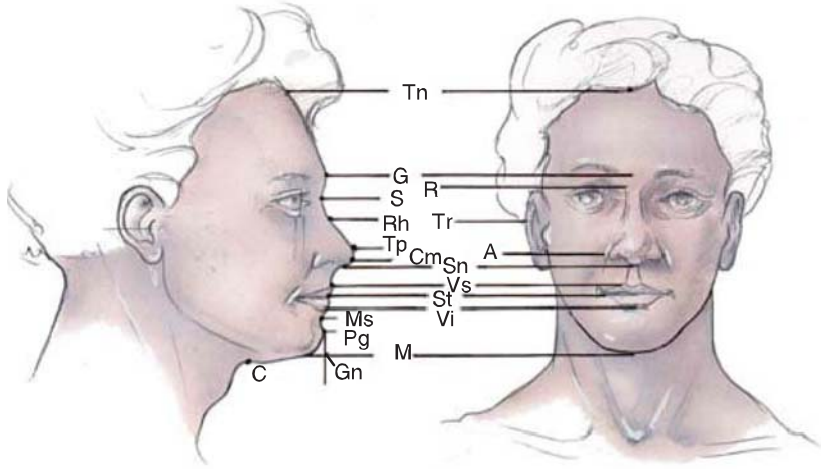

Figure 170.2 Basic anatomic landmarks for facial analysis. See Tables 170.2 and 170.3 for explanation.

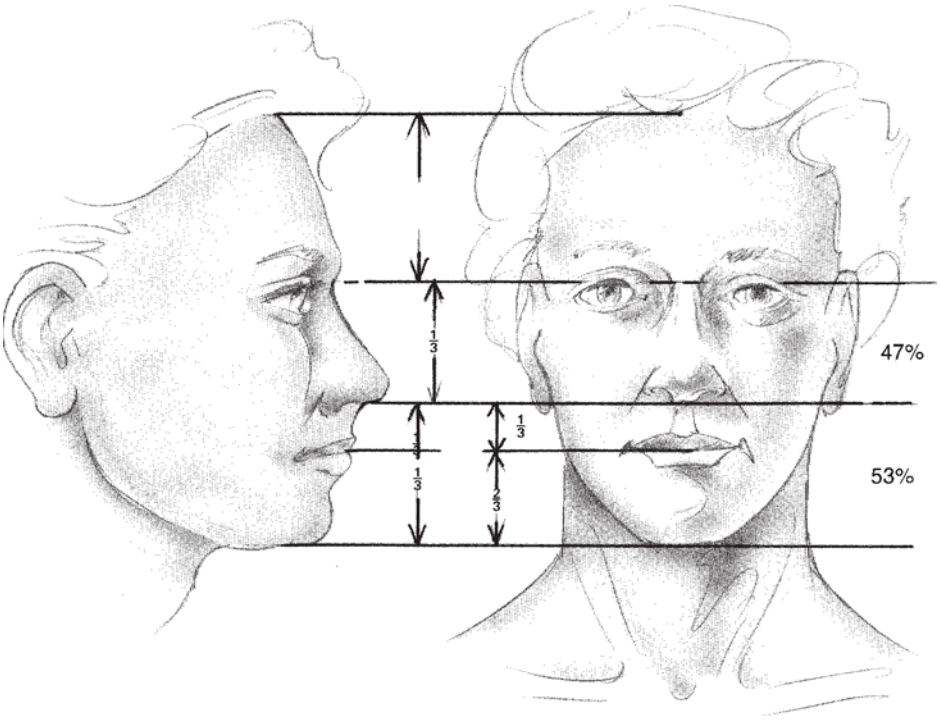

Figure 170.4 The facial thirds: trichion to glabella, glabella to subnasale, subnasale to menton. The lower face also is divided into thirds: The upper lip from subnasale to stomion is one-third, and the lower lip and chin is two-thirds. The face from nasion to subnasale is 47% and from subnasale to menton is 53% of the total height from nasion to menton. (From Powell N, Humphries B. *Proportions of the aesthetic face.* New York: Thieme-Stratton, 1984, with permission.)

then divided into horizontal thirds at the glabella and the subnasale. This creates an upper third from trichion to glabella, a middle third from the glabella to the subnasale and a lower third from subnasale to menton.

Lower facial symmetry can be further assessed by subdividing this region in thirds as well. The upper third is equal to the distance from the subnasale to the stomion, while the lower two-thirds are equal to the distance from the stomion to the menton (33).

The facial profile assessment examines the relationships of individual components to the face as a whole. Lateral view assessment begins with positioning of the patient in the Frankfort horizontal (Fig. 170.5) (Tables 170.3 and 170.4). When a line from the inferior orbital rim to the tragion is parallel to the horizon, the patient is said to be in the Frankfort horizontal. This provides a reproducible posture for comparison between patients and over time.

Gonzales-Ulloa (34) described a useful method of evaluating the aesthetic profile in relation to the Zero Meridian line. This vertical line passes through the nasion perpendicular to the Frankfort horizontal line. In the aesthetically pleasing facial profile, the outline of the midforehead, subnasale, upper and lower lips, and pogonion should rest on this line. The Zero Meridian and Frankfort horizontal line provide a framework from which to analyze the facial profile. The frontal, nasal, labial, and mandibular regions can be analyzed for protrusion or retrusion based on their relationships to these lines. In addition to providing a qualitative assessment of aesthetic units on profile view, this technique also allows the surgeon to quantify the amount of correction needed in each area.

Forehead

The forehead occupies one-third of the vertical height of the face and is a significant contributor to overall facial balance. The forehead is defined as the space between the

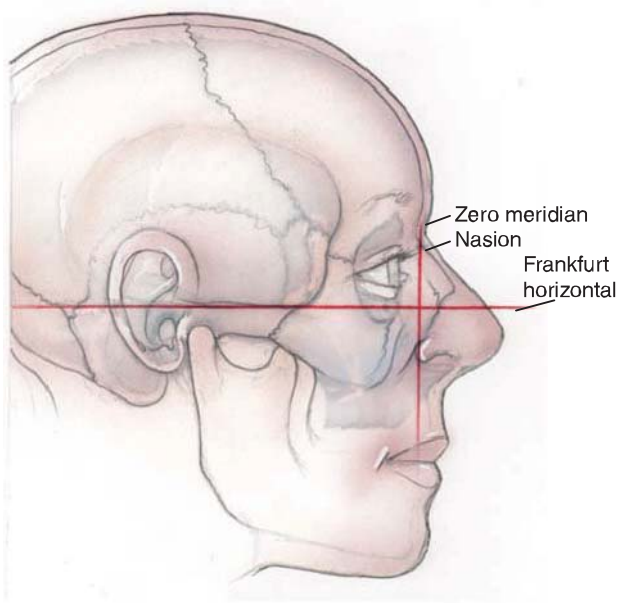

Figure 170.5 The Frankfort horizontal plane connects the inferior orbital rim to the tragion and is parallel to the horizon. Gonzalez-Ulloa defined the aesthetic profile in relation to the Zero Meridian, a line perpendicular to the Frankfort horizontal plane through the nasion. In the aesthetically pleasing profile, the outline of the midforehead, subnasale, upper and lower lips, and pogonion rest on this line (From Gonzalez-Ulloa M. Quantitative principles in cosmetic surgery of the face (profi leplasty). *Plast Reconstr Surg Transplant Bull* 1962;29:186–198.).

TABLE 170.3 BASIC ANATOMIC LANDMARKS ON LATERAL VIEW

Nasion (N)	Posteriormost bony point at the root of the nose
Sellion (S)	Posteriormost soft tissue point at the root of the nose
Glabella (G)	Anteriormost point of the forehead in the midline
Rhinion (Rh)	Region at the junction of the bony and cartilaginous nasal dorsum
Tip-defining-point (Tp)	Anteriormost projection of the nasal tip, corresponding to the dome of the lower lateral cartilages
Columellar point (Cm)	Anteriormost point of the columella
Alar crease (A)	Sulcus defining the posterior border of the alar subunit of the nose
Mentolabial sulcus (Ms)	Crease between the lower lip and chin
Pogonion (Pg)	Anteriormost point of the chin in the midline
Gnathion (Gn)	Virtual point defined by the intersection of a vertical line lying tangent to the pogonion and a horizontal line that is tangent to the menton.
Cervical point (C)	Virtual point defined by the line tangent to the anterior margin of the neck and a line tangent to the menton
Tragion (Tr)	Point at the supratragal notch of the ear

trichion and the glabella, bordered by the hairline superiorly and laterally, and extending upward from the superior aspect of the eyebrows. The shape of the forehead varies between men and women, and consequently the most aesthetically pleasing contour is gender-dependent. The attractive female forehead contour has a gentle convexity on profile with its most anterior point at the supraorbital ridge lying tangent to the Zero Meridian. Men tend to have a more protruding forehead than women with a degree of supraorbital bossing. The shape of the forehead is also important in the context of the global facial appearance. A protruding forehead will draw more attention to a recessed chin or maxilla and vice versa.

One of the most important aspects of the forehead from a surgical standpoint is the nasofrontal angle (NFA). The NFA is an obtuse angle formed by lines tangent to the glabella and nasal dorsum. The vertex of this angle is the sellion, and the normal value of the NFA varies from 115 to 135 degrees (Fig. 170.6). The vertex of the NFA lies at the level of the superior limbus of the eye, though this is variable. Men tend to have a more acute NFA when compared to females, due to the increased prominence of the supraorbital rim. Thus, in men the NFA ideally measures 115 to 120 degrees whereas women ideally measure 120 to 135 degrees. Changing the position of the NFA can have dramatic effects on the harmony of surrounding structures. Additionally, the length of the nose is determined by the vertical position of the NFA; a factor that can be addressed with surgery. Moving the vertex of the NFA superiorly lengthens the nose and vice versa. The infantile nose deformity occurs when telescoping naso-orbito-ethmoid fractures result in a posterior repositioning of the NFA. This leads to a loss of nasal dorsal height that resembles the undeveloped dorsum of a child.

TABLE 170.4 PROFILE PLANES AND ANGLES USED IN FACIAL ANALYSIS

Facial Plane	Reference plane created that is tangent to the glabella and pogonion
Frankfort Horizontal	Reference line from the superior margin of the external auditory canal to the inferior border of the infraorbital rim
Zero-Meridian	Reference line perpendicular to the Frankfort Horizontal intersecting at the nasion
Nasofrontal angle (NFA)	Obtuse angle formed by lines tangent to the glabella and nasal dorsum with the vertex at the sellion
Nasofacial angle (NFcA)	Angle of inclination of the nasal dorsum from the facial plane
Nasolabial angle (NLA)	Angle of inclination between the columella and the upper lip
Lower Face-Throat Angle	Angle formed at the gnathion by the intersection of a line from the cervical point to menton with a line from the subnasale to the pogonion.
Mentocervical angle (MCA)	Angle formed by the intersection of a line from the cervical point to menton with a line from the glabella to pogonion.

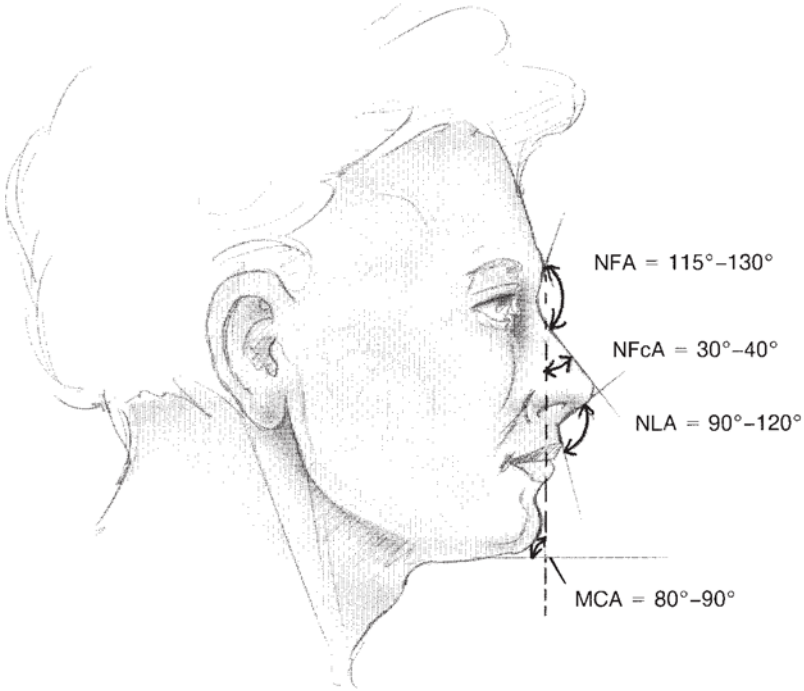

Figure 170.6 Profile angles for facial analysis. See Table 170.4 for definitions.

Eyebrow

The eyebrows function in static protection of the eye, facial identity, and sexual dimorphism. They also convey expressions of happiness, surprise, and anger distinctly from the rest of the face (35). With aging, the brow position descends due to the affect of gravity and accumulated skin damage. Eyebrow size, position, and morphology change dramatically throughout one's life, and normative values are useful when performing an aesthetic evaluation.

The female brow is positioned at or above the supraorbital rim with an arch that peaks in the lateral third of the brow. In contrast, the male brow is positioned directly over the supraorbital rim and is relatively straight (36,37). The contemporary concept of the ideal position of the male eyebrow has remained fairly constant, but the same cannot be said for the female brow. In 1974, Westmore proposed that the aesthetic female eyebrow begins medially over the alar groove and ends laterally at a line connecting the lateral canthus and the lateral ala. The author also conjectured that the medial and lateral aspects of the eyebrow should fall in the same horizontal plane and that the apex of the eyebrow lies above the lateral limbus (36,38,39). Over the last few decades, several authors have offered modifications to Westmore's paradigm following the shifting aesthetic ideals of society. Cook et al. (40) concluded that the peak of the eyebrow belongs over the lateral canthus rather than the lateral limbus. Most recently, Roth et al. evaluated the frontal photographs of fashion models and randomly selected women. Their findings suggest that the ideal eyebrow arch position lies between the lateral limbus and lateral canthus. The authors also found that the lateral brow lies slightly superior to the medial brow in the horizontal plane (41) (Fig. 170.7).

Eyes/Eyelids

The eyes are the seat of beauty, and changes in this region, whether age-related or otherwise, often prompt patients to seek aesthetic evaluation. Appraisal of facial harmony requires close examination of the symmetry, shape, proportions, and position of the eyes. The medial limbus of the iris ideally lies on a vertical line with the oral commissures. In Caucasians, the intercanthal distance should be equal to the interalar width of the nasal base. However, this is not true for Asian or African Americans, who typically

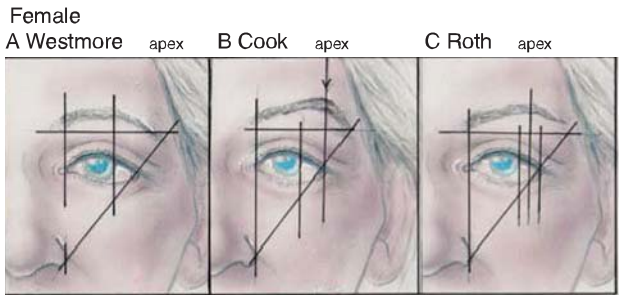

Figure 170.7 **A:** The ideal brow begins at the medial canthus and ends laterally along an oblique line through the alar–facial junction and the lateral canthus. Westmore proposed that the apex of the eyebrow should reach its maximal arch along a line tangent to the lateral limbus. (Adapted from Brennan GH. Correction of the ptotic brow. *Otolaryngol Clin North Am* 1980;13:265–273, with permission.) **B:** Cook Modification: With shifting societal aesthetic ideals, the aesthetic position of the female brow has also shifted. Cook proposed that the peak of the eyebrow lies over the lateral canthus rather than the lateral limbus. **C:** Roth Modification: Most recently, Roth et al. found the ideal eyebrow arch position lies between the lateral limbus and lateral canthus and that the lateral brow lies slightly superior to the medial brow in the horizontal plane.

have a slightly wider interalar distance. The average intercanthal distance is 32 to 35 mm, whereas the average interpupillary distance is 61 to 69 mm (42). The interpupillary and intercanthal distances are approximately equal to the width of one eye (43).

The contour of the youthful upper and lower eyelids is one of smooth transitions. The upper eyelid has a definable supratarsal crease (STC) and then flows smoothly to the brow above. The lower eyelid transitions without demarcation into the malar eminence and cheek. The upper eyelid overlies the superior limbus by 2 to 3 mm, whereas the lower lid approximates or overlies the inferior limbus by 1 mm. The apex of the supratarsal plate is centered over the medial limbus, while the nadir of the lower eyelid lash line is aligned with the lateral limbus (44) The distance from lash line to lid crease on the upper lid varies from 7 to 15 mm in the non-Asian patient (32), but tends to be greater in men than in women. The lateral canthus lies 2 to 4 mm above the medial canthus (45) yielding an upward tilting intercanthal axis that is characteristic of the beautiful eye. Many anatomical variations exist based on gender, ethnicity, and body habitus. In addition, soft tissue volume is lost with aging, which disrupts the smooth transitions of the eyelid leading to dermatochalasis and periorbital wrinkles and folds (Fig. 170.8).

Ears

Ridges and concavities in the auricular cartilage framework form the distinctive shape of the external ear. The auricle reaches 80% of the adult size by age 5 (46), permitting early surgical intervention using adult normative values. When analyzing the ears, each auricle is evaluated relative to the face and individually, as deformities can be distinct between each ear.

The position of the auricle on the head contributes distinctly to overall aesthetics. The top of the ear should lie at the level of the brow and the bottom of the lobule at the nasal ala (47). The axis of the ear slants posteriorly and approximates the inclination of the nasal bridge. The helix forms the most lateral extent of the auricle on frontal view and should be just visible behind the antihelix and superior crus.

The width of the ear is approximately 55% its length. The average length and width of the male auricle is 63.5 and 35.5 mm, respectively. Corresponding measurements in the female are 59.0 and 32.5 mm (48,49). When viewed from above, the auricle protrudes 20 to 30 degrees from the skull. In assessing ear protrusion, the distance from the mastoid to the helix is recorded at the superior aspect of the helix, at the level of the external auditory canal, and at the lobule. The ideal values for these distances in the adult should be 16 to 18 mm, 14 to 16 mm, and 16 to 18 mm, respectively.

Nose

With its central location on the face, the nose is one of the most important contributors to facial aesthetics. No other feature must harmonize with other areas of the face more than the nose. Small changes to the nose can produce dramatic differences in overall facial aesthetics. For this reason, it is one of the most frequently surgically altered features and the normal proportions of the nose have been thoroughly documented. Ideal aesthetics occur when nasal proportions and angles are within normal limits and

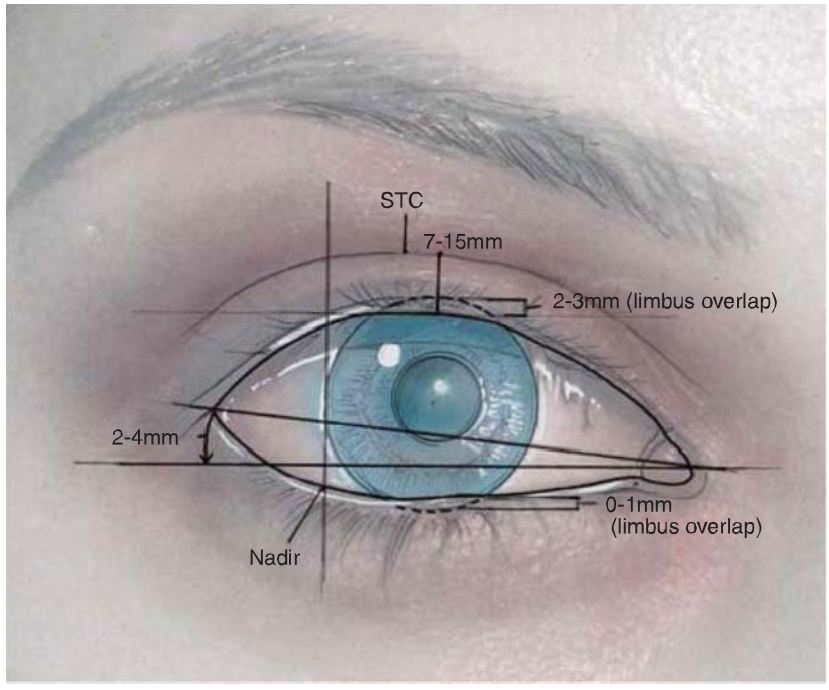

Figure 170.8 Characteristic relationships of the aesthetically pleasing eye. The upper eyelid overlaps the superior limbus of the iris by 2 to 3 mm, while the lower eyelid approximates or overlaps the inferior limbus by 1 mm. The supratarsal plate is tallest at the medial limbus. The nadir of the lower eyelid lash line is aligned with the lateral limbus. The distance from the upper eyelid lash line to the supratarsal crease (STC) varies from 7 to 15 mm. The intercanthal axis is tilted upward laterally, with the lateral limbus lying 2 to 4 mm above the medial canthus.

harmonize with other facial features. However, more than with any other facial feature, variations of the nasal proportions are accepted based on ethnicity, age, height, and gender.

Nasal Angles

Several angles are useful in defining the relationship of the nose to the face. As discussed above, the NFA is important in the aesthetics of both the nose and the forehead. It describes the superior limit of the nose and can have a dramatic effect on the overall appearance of the nose.

The nasofacial angle (NFcA) describes the relationship of the nasal dorsum to the facial plane, defined by a vertical line from the glabella to the pogonion. The NFcA is formed by the intersection of a line from the sellion to the nasal tip (drawing through any dorsal hump that may exist) with the facial plane. A NFcA of 36 degrees is aesthetically ideal and can help to determine whether to augment or reduce the nasal dorsum.

A third angle of measurement helpful in the nasal–facial aesthetics is the nasolabial angle (NLA). The NLA is formed by lines constructed from the superior vermilion border to the subnasale, and from the subnasale to the columella. This angle defines the relationship between the nose and the upper lip as well as the rotation of the nasal tip. An aesthetically pleasing NLA is 90 to 95 degrees in men and 95 to 105 degrees in women. Shorter individuals tolerate a more obtuse angle, whereas taller people require a NLA at the low end of the range for their gender (Fig. 170.6, Table 170.4).

Nasal Tip Projection

Many techniques have been proposed to define ideal nasal tip projection and controversy exists over which method is optimal. Also, one must differentiate between tip projection and rotation as they are closely related, but distinct concepts. Tip rotation is the caudal or cephalad rotational movement of the tip around the fixed point of the tragion. Nasal tip projection, on the other hand, is the anterior or posterior positioning of the nasal tip relative to the Zero Meridian (Fig. 170.9).

There are four methods commonly used to evaluate tip projection. Perhaps the simplest method was proposed by Simons in 1975 (50). He suggested that the distance from the upper lip vermilion border to the subnasale and from the subnasale to the tip defining point should be approximately equal. This method is easy to perform and takes into effect harmony with a nearby structure. However, the variable size of the upper lip length can yield inaccurate results.

Powell and Humphries described the ideal relationship between tip projection and nasal height as a 2.8:1 ratio. Height is measured from sellion to subnasale, and tip projection is measured by a line drawn perpendicular to the first line through the tip defining point (33) (Fig. 170.10). Though relatively simple, this method does not take into account the effect the length of the ala on tip projection.

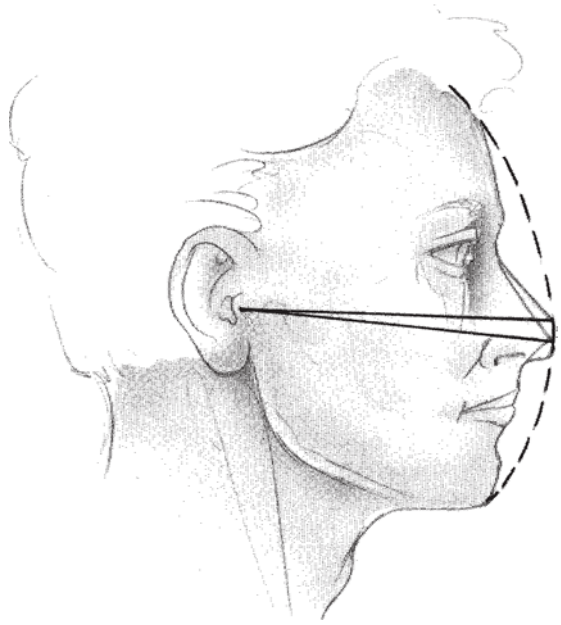

Figure 170.9 Nasal tip rotation is defined by the movement of the nasal tip on an arc around the tragion.

Goode's method of assessing tip projection takes into account the relationship between nasal length and the alar groove. A vertical line is drawn from the sellion through the alar groove. A second perpendicular line is then drawn to the

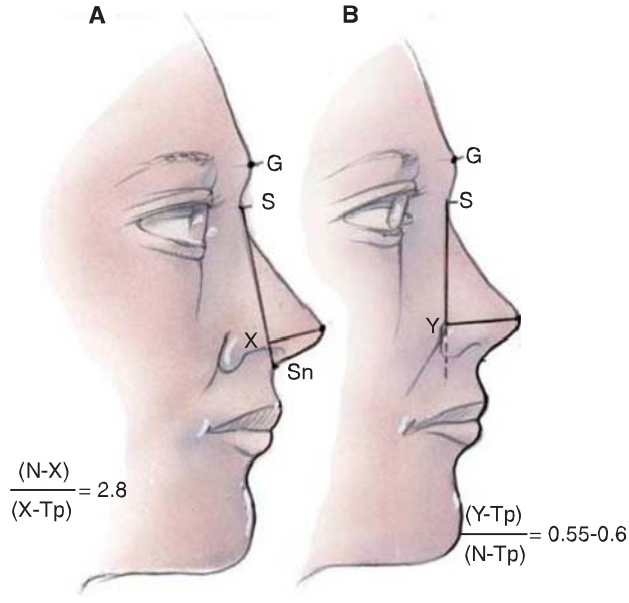

Figure 170.10 Assessment of nasal projection. **A:** The Powell and Humphries (33) method. A line from sellion (S) to subnasale (Sn) is used to measure tip projection. The ratio of projection (X-Tp) to height (S-X) is ideally 2.8:1. **B:** The Goode (51) Method. A line from sellion (S) to the alar groove is used to measure tip projection. The ratio of projection (Y-Tp) to length (S-Tp) is ideally 0.55 to 0.6:1.

tip defining point, which effectively measures tip projection starting from the most posterior feature of the nose. Lastly, nasal length is determined using a line from the sellion to the tip (Fig. 170.10). The ideal ratio of tip projection to nasal length with the Goode method is 0.55 to 0.6:1, which produces a NFcA of 36 to 40 degrees. Crumley and Lanser (52) took this one step further by defining the relationship of tip projection, nasal length, and vertical height as a right triangle whose sides have a 3:4:5 ratio. With these parameters, the NFcA also approximates the ideal 36 degrees.

Nasal Width

The nasal width may be described as the distance between the alar grooves. The relationship of nasal base with the rest of the face is best evaluated on frontal view, where the width of nasal base should equal the width of one eye. If the distance between the medial canthi is proportionate (i.e., one eye width), then drawing a vertical line down from the medial canthus should pass through the alar groove. This technically easy evaluation can be performed during the consultation to determine if corrective surgical maneuvers are needed. A second method involves first calculating the nasal length from sellion to the tip defining point. A proportionate nasal width is estimated at 70% of the total length.

The basal view is also used to assess nasal width as well as nasal tip symmetry. On basal view, the nose should have the appearance of an equilateral triangle (53). The width of the nasal lobule should be 75% of the width of the entire nasal base. The width of the columella compared to the width of the lobule should be 2:1. The tip should comprise one-third of the total height, while the nostrils make up the remaining two-thirds on basal view (Fig. 170.11). The nostril openings are ideally ovoid and obliquely oriented toward the tip. The posterior aspect of the nostril is slightly larger and rounder, becoming more narrow anteriorly (54). Careful assessment of the individual components of the nasal base allows for a site-specific analysis of the contributors to overall nasal width and symmetry.

Lateral View Nasal Assessment

The lateral view of the nose allows one to assess the nasal profile and the ala-tip complex. On lateral view, the length of the ala and tip should be equal, though tip lobular excess is more acceptable than alar excess (53). There should be 2 to 4 mm of columellar show below the level of the nostril rim on profile view (Fig. 170.11). The elegant nasal tip profile has a "double break" produced by the tip defining point anteriorly and a subtler angulation at the junction of the tip lobule with the columella. Additionally, a supratip break exists between the nasal tip subunit and the nasal dorsum in the ideal nose. Although ethnic variations exist, a more pronounced supratip break is more acceptable in women than in men. The distance from the long axis of the nostril to the alar rim and columella should be 1 to 2 mm. Discrepancies from this ideal indicates alar or columellar retraction, or a hanging ala or columella (55).

Midface

The soft tissues of the midface provide much of the contour that gives an individual their unique facial appearance (56). While direct measurements and angles are used to define ideals in other areas, aesthetic evaluation of the midface region is more heavily reliant on symmetry and harmony with surrounding features.

The appearance of the midface is highly dependent on the underlying bone structure, fat compartments, and skin texture. The face should be widest at the zygomaticus, the most prominent portion of the zygomatic arch, and should taper down to the chin, giving the face a heart-shaped appearance. The malar eminence ideally lies within the space defined by a line from the nasal base to the tragus and a line from the oral commissure to the lateral canthus (57).

The soft tissue envelope of the midface is uniquely susceptible to solar damage, gravity, and the aging process. With

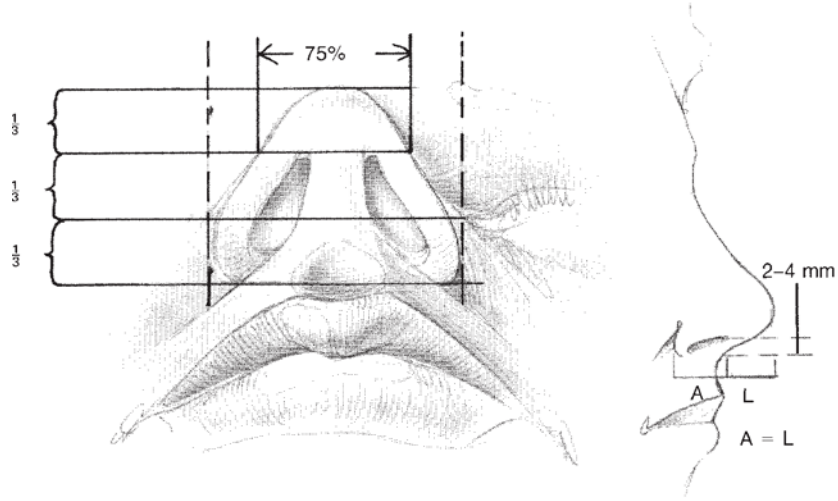

Figure 170.11 The width of the nasal lobule should be 75% of the width of the nasal base. The lobule-to-columella ratio should be 1:2. On lateral view, the ala-to-lobule ratio should be 1:1, and there should be 2 to 4 mm of columellar show.

aging, the skin and soft tissues of the midface atrophy and descend. This leads to the formation of jowls and a "squaring off" of the heart-shaped face of youth. To determine the best restorative approach for the midface, an assessment must be made of midfacial volume, skin laxity, and the prominence of the nasolabial and nasojugal folds (58,59).

Chin

The chin plays a prominent role in the balance of the facial profile. Classically, a prominent chin is associated with strength and power, whereas a retrusive chin portrays weakness. The chin extends from the mentolabial sulcus to the menton. The lower lip and chin should make up two-thirds of the total length of the lower third of the face, with the upper lip making up the other one-third. Although the chin is a distinct feature, an alteration to its architecture also changes the lower lip and neck profile.

As described above, the pogonion of the masculine chin should approximate the Zero Meridian (34). In women, the pogonion should fall just behind this line (Fig. 170.5). The relationship of the chin to the lower face is assessed with a vertical line from the lower vermilion border of the lip. In men, the pogonion is tangent to this line with the mentolabial sulcus lying 4 mm posteriorly. In women, this line should lie 2 to 3 mm anterior to the pogonion. Prognathia or retrognathia are defined by deviation of the pogonion from these positions.

Lip

The lips are an essential component of beauty and aid in the display of emotion, personality, and sexuality. In Western culture, full lips with a well-defined philtrum are associated with youth and beauty, while a thin vermilion with diminished lip highlights are signs of aging (60). The lips have an intimate relationship with the chin, nasal base, premaxilla, and teeth, which can alter their position and global facial aesthetics.

To achieve facial balance, the vertical length of the upper lip from subnasale to stomion should equal one-third of the lower facial third, whereas the lower lip and chin from stomion to menton should compose two-thirds of the lower facial third. With the lips slightly parted, there should be a maximum of 2 mm of maxillary incisoral show (61). The upper and lower lip should just appose with the teeth in occlusion and the lips relaxed. No more than two-thirds of the maxillary incisor should be exposed on full smile (62). Although gingival show was historically considered undesirable, a small amount on smile is acceptable in contemporary society (63).

The youthful projection of the lips can be determined using a line from the subnasale to the pogonion. Burstone (64) found that ideal aesthetics were obtained when the most anterior aspects of the upper and lower lips lie 3.5 and 2.2 mm anterior to this line, respectively. This provides for a subtle youthful "pout" of the lips (Fig. 170.12).

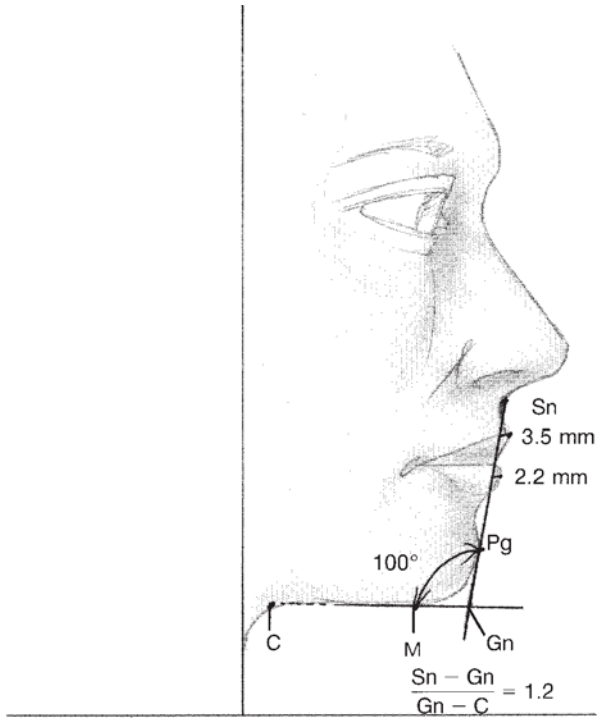

Figure 170.12 The most anterior point of the upper lip should be 3.5 mm, and that of the lower lip should be 2.2 mm, from the Sn-Pg line. Legan and Burstone (65) described the lower face–throat angle (*Sn-Gn-C*), which should be 100 degrees. The lower facial height (*Sn-Gn*) to depth (*Gn-C*) ratio should equal 1.2:1.

The height of the white upper lip, the soft tissue between the nasal base and the vermilion border, is greater in men than in women. The most prominent feature of the white lip is the philtrum (from Greek: philtron, meaning "love charm") (61). A well-defined philtrum is associated with youth and contributes to the "cupids bow" appearance of the vermillion border.

Neck

A well-contoured neckline has long been associated with elegance and beauty. The neck is intimately related to the chin, lips, and lower face and must be evaluated relative to these structures. The lower face-throat angle (65) describes the relationship of the chin to the neck. It represents the extent to which the submental tissues are tucked beneath the chin. Connecting lines from the cervical point to the menton, and from the subnasale to the pogonion forms the lower face-throat angle. The intersection of these lines is a virtual point called the gnathion. The lower face-throat angle is ideally 90 to 105 degrees. The mentocervical angle (MCA), described by Powell and Humphries, is a tool that better describes the relationship of the neck to the face. Rather than using the subnasale as a point of reference, the MCA is constructed from the glabella. This produces an angle that takes into account a broader area of the facial profile (Fig. 170.12).

The values of the MCA and lower face-throat angle are reliant on the relationship of the hyoid bone to the

anterior mandible (66). The relative position of these anatomic entities to one another represents the limiting factor in attempts to surgically manipulate the neckline (67). An inferiorly and anteriorly positioned hyoid limits the amount that the submental tissues can be drawn up under the mandible. Conversely, a relatively posterior and superior position of the hyoid bone allows for a more acute MCA and lower face-throat angle, yielding a more aesthetically pleasing neckline.

Equally important in analysis of the neckline is evaluation of the neck skin and soft tissues. Blunting of the MCA is commonly caused by age-related skin laxity, proliferation of fatty deposits, and platysma muscle banding. These common culprits should be noted during consultation so that an appropriate treatment plan can be formulated (68).

METHODS OF FACIAL ANALYSIS

Cephalometrics

Orthodontists and oral maxillofacial surgeons traditionally favor the use of cephalometrics to plan treatment and evaluate their results. This method involves measurement of the maxillary, mandibular, and dental relations on lateral radiographs of the face and skull base. A cephalostat is used to hold the head in a fixed position to take the radiographs. Once obtained, soft tissue and skeletal landmarks are traced to plot points, lines, and angles, which are then used to evaluate the anterior–posterior position of the jaws and teeth in reference to the cranium and each other. Numerous systems of cephalometric analysis have been proposed and each incorporates a set of reference values for the assorted linear and angular measurements. Although the various measurements required in this method are elaborate, time-consuming, and labor intensive, it is an excellent method for evaluating craniofacial and orthognathic relationships.

Photometrics

Direct evaluation of soft tissue proportions on facial photographs, as opposed to radiographic craniofacial relations, is the method preferred by most facial plastic surgeons. In part, this is because skeletal repositioning maneuvers evaluated by cephalometric means are not absolutely correlated with a similar change in the overlying soft tissue. It is also extremely convenient to use photograph and video images to assess facial proportions and to compare the pre- and postoperative results. Similar to cephalometrics, multiple angles and ratios between the aesthetic units are calculated based on the photographic profile. An excellent summary of several cephalometric and photometric analysis systems can be found in Powell and Humphries (33) and in Chapter 171.

Three-Dimensional Photography

Facial plastic surgeons have long relied on photography for preoperative and postoperative analysis, medical-legal documentation, and communication. However, photometric techniques only allow for the measurement of two-dimensional distances, angles, and areas. Additionally, surgical outcomes are somewhat subjective because of the difficulty in quantifying three-dimensional change on a two-dimensional photograph (69).

Recently-developed three-dimensional imaging technology allows for accurate measurement of soft tissue volumetric data and surface topography (70). The technique of acquiring 3-D photographs is technically easy and can be completed in the office setting. Most camera systems utilize six cameras (3 on each side) positioned in front of the patient at oblique angles. All six cameras fire simultaneously and the images are acquired in less than 2 milliseconds. Computer software processes the images producing a mesh framework onto which the soft tissue contours and colors of the skin are applied (Fig. 170.13).

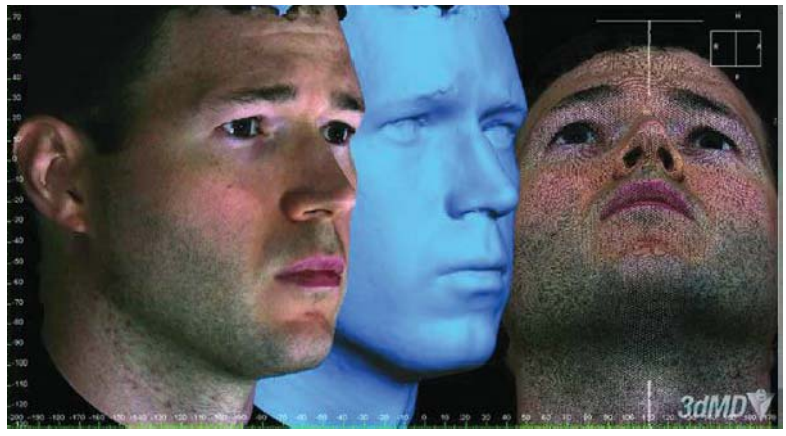

Figure 170.13 Three-dimensional photography. Three-dimensional photography allows for accurate measurement of soft tissue volume changes and surface topography. (3-D image courtesy of 3dMD (Atlanta) www.3dmd.com)

Once the image has been rendered, the physician can accurately measure angles and distances from any anatomic landmark on the face. Multiple studies have proven the accuracy of these measurements in comparison to standard techniques (71).

In addition to standard measurements, the three-dimensional aspect of the photograph allows the surgeon to evaluate changes in facial volume. The effects of aging and volume changes following surgery can therefore be quantified. By performing serial 3-D photographs and superimposing each photograph onto the original image, a topographical "color map" is created displaying changes in facial volume to cubic millimeter resolution (69). The ability to quickly and noninvasively quantify the face three dimensionally is a major advance in facial plastic surgery representing the future of aesthetic facial analysis.

CONCLUSION

Cosmetic facial surgery is more commonplace in Western society than ever before. The widespread availability of information via the Internet, social media, and other means allows today's patients to be very well informed about the procedures they seek. Now, more than ever, surgeons must be knowledgeable about what constitutes normal facial features and must be tactful in dismissing misconceptions regarding deformity and facial harmony.

During the initial consultation, establishing good rapport is necessary in order to understand the motivations for seeking plastic surgery and whether a psychiatric illness exists. Expectations from surgery are clearly identified to determine if they are realistic, reasonable, and obtainable. Once this information has been gathered, the face is analyzed from an aesthetic standpoint. Aesthetic evaluation requires an understanding of the concepts of facial harmony, proportion, and symmetry. This process begins with an overall assessment of facial symmetry, followed by a stepwise examination of the individual aesthetic masses. Each facial feature should be evaluated based on its relationship to the face globally and on feature-specific normative values. Understanding what constitutes normal helps to determine if concerns about a deformity are valid or due to psychopathology, such as BDD.

Modern facial plastic surgeons now have a variety of methods to carry out facial analysis. The traditional methods of cephalometrics and photography, though widely used are being replaced by more advanced three-dimensional photography. This technology is a major advance in facial analysis and is changing the way facial plastic surgeons analyze the face, quantify outcomes, and communicate with their patients.

HIGHLIGHTS

- Properly selecting patients for facial plastic surgery is essential to preventing unhappy patients. The surgeon must understand the patient's expectations, whether they are reasonable, and whether the desired result can be delivered.
- Although proportionate features are more likely to be aesthetically pleasing, disproportionate features can still engender a pleasing overall appearance by creating harmony with one another.
- The SAGA tool helps to uncover the patient's perception of deformity and its impact on them.
- The rate of psychopathology in cosmetic surgery patients today approaches that of the general population.
- It is generally accepted that patients with a preoperative diagnosis of depression can undergo cosmetic surgery without fear of long-term intensification of their symptoms.
- BDD is characterized by an unhealthy obsession with one or more body parts. Patients with BDD have a preoccupation with some slight or perceived flaw in their physical appearance and cannot be effectively treated with surgery.
- A system of objective measurements rather than simple subjective assessment is important in communicating the degree of deformity and surgical corrective goals with the patient.
- Facial analysis should begin with the assessment of overall facial symmetry. The face is divided into horizontal thirds and vertical fifths; asymmetries should be pointed out to the patient preoperatively.
- The profile is assessed with the patient in the Frankfort Horizontal position. The Zero Meridian line passes through the nasion perpendicular to the Frankfort horizontal line and is useful in examining profile relationships. The outline of the midforehead, subnasale, upper and lower lips should rest on this line.
- The pogonion in men should approximate the Zero Meridian and in women should fall just behind this line.
- An evaluation of the interfacial proportions of the profile involves calculating the nasofrontal, nasofacial, nasomental, and MCAs.
- The NFA is an obtuse angle formed by lines tangent to the glabella and nasal dorsum. The vertex of this angle is the sellion, and the normal value of the NFA varies from 115 to 135 degrees.
- The ideal eyebrow position is at the orbital rim in men and slightly above the rim in women. The

contemporary concept of the ideal position of the apex of the eyebrow has changed over the last several decades; it has been described in line with the medial limbus, lateral canthus, or between these two points.

- The eyes are the seat of beauty. The medial limbus of the iris should lie on a vertical line with the oral commissures and the interpupillary and intercanthal distances are approximately equal to the width of one eye.
- The position of the auricle contributes distinctly to overall aesthetics. The helix forms the most lateral extent of the auricle on frontal view and should be just visible behind the antihelix and superior crus.
- Due to its central location on the face, even small changes to the nose can have dramatic effects on overall facial aesthetics. Ideal aesthetics occur when nasal proportions and angles are within normal limits and harmonize with other facial features.
- On lateral view, the length of the ala and tip should be equal with 2 to 4 mm of columellar show below the level of the nostril rim. The elegant nasal tip profile has a "double break" produced by the tip defining point anteriorly and a subtle angulation at the junction of the tip lobule with the columella. A supratip break exists between the nasal tip subunit and the nasal dorsum.
- On basal view, the nose ideally has the appearance of an equilateral triangle and the width of the nasal lobule is 75% of the width of the entire nasal base.
- The soft tissue envelope of the midface is uniquely susceptible to solar damage, gravity, and the aging process. Descent of the midfacial skin and soft tissues with aging leads to the formation of jowls and a "squaring off" of the heart-shaped face of youth.
- Though popular, cephalometric and photometric analyses lack the ability to evaluate the face in three dimensions or quantify volumetric change. Three-dimensional photo systems allow the surgeon to perform more sophisticated measurements and to quantify surgical outcomes.

171 Pictorial Documentation: Digital Imaging and Traditional Photography

Andrew K. Patel *Amir M. Karam* *Samuel M. Lam*

Pictorial documentation—whether film or digital based—serves multiple important purposes for the head and neck surgeon: medicolegal documentation, physician–patient communication, preoperative planning and intraoperative reference, lay and professional education, and physician self-education. In particular, the subfield of facial plastic and reconstructive surgery relies heavily on the need for standardized photographs for all of the above reasons. Photography in facial plastic surgery must be accurate, consistent, and of high quality to be useful. Photos should be free of distortion, with the greatest possible depth of field (DOF). In contrast to a studio portrait, the goal is not to make the patient appear as good as possible but rather to represent the patient as accurately as possible. Accordingly, this chapter focuses on the principles of good medical photography that relate, for the most part, to cosmetic and reconstructive facial surgery. Nevertheless, all the topics discussed can be easily applied across the broad spectrum of head and neck surgery, as indicated. The emerging and now well-established role of digital photography is also reviewed in depth and contrasted against traditional 35-mm photography to help the surgeon decide which format is better suited for his or her practice.

PRINCIPLES OF PHOTOGRAPHY

Rather than divide this section into digital and 35-mm film photography, the basic fundamental tenets that underscore good photography are universally applicable and can be discussed without reference to a chosen format. The primary spotlight will remain on good pre- and postoperative portrait photography, as this subject represents one of the most challenging and vital for the surgeon to undertake correctly. However, some practical tips on quality intraoperative photographs will also be outlined.

Informed Consent

Respect for a patient's privacy is of paramount importance for both ethical and legal grounds. Medical records should be thought of as a systemic documentation of an individual's medical history. The data contained in the physical chart or photographs is also the medical record separate from its physical embodiment. Though it may seem academic to distinguish the physical document from the information it contains, the distinction is important and relates to ownership. In the United States, patients own the information about their medical past and treatment contained in the physical form. However, the medical provider owns the physical or electronic structure that houses the information. Therefore, when discussing patient photographs, the patient actually controls the data contained in the images unless there is a legal agreement to the contrary. Use of patient photography for media or educational purposes should always be preceded with a thorough and explicit written consent. For instance, now with the rise of the Internet as a ubiquitous medium, consent forms should reflect every medium in which the surgeon intends to use the photographs, including print, television, in-office, Internet, etc. The surgeon can also state that the photograph will be used only for educational purposes and restrict the use of those photographs explicitly to scientific lectures and/or scientific articles. Further, the patient may be offered the option to camouflage his or her identity by blackening out the eyes, using only one angle of view, or cropping the image in a certain prescribed way—all of which should be stated clearly in the consent and with which the surgeon should comply. The surgeon should also guarantee in the consent that the patient's name and identity will not be further revealed unless otherwise stipulated by the patient, for example, as a testimonial.

Standardization

In order for a photograph to carry any meaningful significance, the photographs must be standardized in the following manner: same photographic media, equipment, and settings; consistent patient positioning and absence of distracting elements (makeup, jewelry, hairstyle); and identical lighting and background. Besides these considerations, the same photographer (physician or staff member) should try to take all of the photographs because slight individual interpretation of these rules can lead to dissimilar photographic results. Before taking the postoperative images, the photographer should also review the preoperative images and then alter the necessary parameters to match the preoperative photographs. For example, if the preoperative oblique view shows that the patient is turned too far laterally, the photographer should try to match the same patient positioning (albeit less than ideal) in order that the postoperative image can be meaningfully compared.

Standardized Equipment

Whether the physician ultimately decides to use film or digital media in his or her practice, the same camera should be used for all "before-and-after" photographs in order to ensure exact reproducibility in the photographic image. In addition, the same camera lens and camera settings (aperture, shutter speed, and exposure values) should be maintained, as any slight deviation can cause a quite obvious disparity in color, contrast, and shadowing. If the surgeon is using film, the exact same film stock should also be used, that is, the brand, film speed, and type (color reversal [slide, transparency] vs. negative) must be preserved.

Standardized Patient Positioning and Related Information

Proper patient positioning is the most demanding aspect of achieving reproducible photographic images. The same camera-to-subject distance must be maintained: this objective can be attained by placing the patient's stool and the camera over prescribed markings on the floor (Fig. 171.1). By using a fixed lens, that is, a lens that has no "zoom" capacity, the physician can also minimize any distortion and variability caused by altering the focal distance. The Frankfort Horizontal Plane must also be observed: the line that runs from the supratragal point through the inferior orbital rim defines the horizontal plane of the image (Fig. 171.2A–C). The Frankfort Horizontal Plane should be respected in the frontal, oblique, and lateral views. The basal view that is mandatory for rhinoplasty, malar augmentation, and midfacial trauma is defined by aligning the tip of the nose with the infrabrow line (Fig. 171.2D). On the oblique view, the patient should also be turned to a certain angle by one of two methods: (a) align the inner canthus of the eye with the oral commissure or (b) align the nasal tip with the malar eminence (Fig. 171.2).

Figure 171.1 Standardized photography requires a dedicated photography room where all pre- and postoperative photographs are taken. A rotating stool with a low or no back is used to rotate the patient's entire body to the prescribed angle for each view. The digital camera is mounted on a tripod with a quick-release head that can easily adjust from a vertical to a horizontal frame position. In turn, the tripod rests on a rolling dolly to facilitate maneuverability. Markers have been placed on the wall to guide the patient how far to rotate the body in the oblique and lateral positions. In this setup, the back leg of the patient's stool contacts the wall, and the tripod's center frame is aligned with the edge of the computer table in order to maintain a standardized camera-to-subject distance. (If flash photography were used, the patient should not be so close to the wall to avoid harsh background shadows.) The back wall is painted a light blue color as a neutral background color.

Whichever method is chosen, the surgeon should attempt to rely on the same method for all images. Another reliable technique to ensure that the patient turns to the correct angle each time is to place markers on the wall that indicate where the patient should turn and face for an oblique and lateral view. When turning to the oblique and lateral positions, the patient should rotate the entire body in alignment with the face and not just turn the head to those positions, which creates neck distortion, especially in the lateral view. A rotating stool with a low back (that does not enter the frame of the image) is ideal for this goal.

One of the most common errors encountered is patient positioning with the neck tilted upward and extended, especially in the more mature patient who wants to reduce the appearance of unwanted neck-tissue redundancy. In

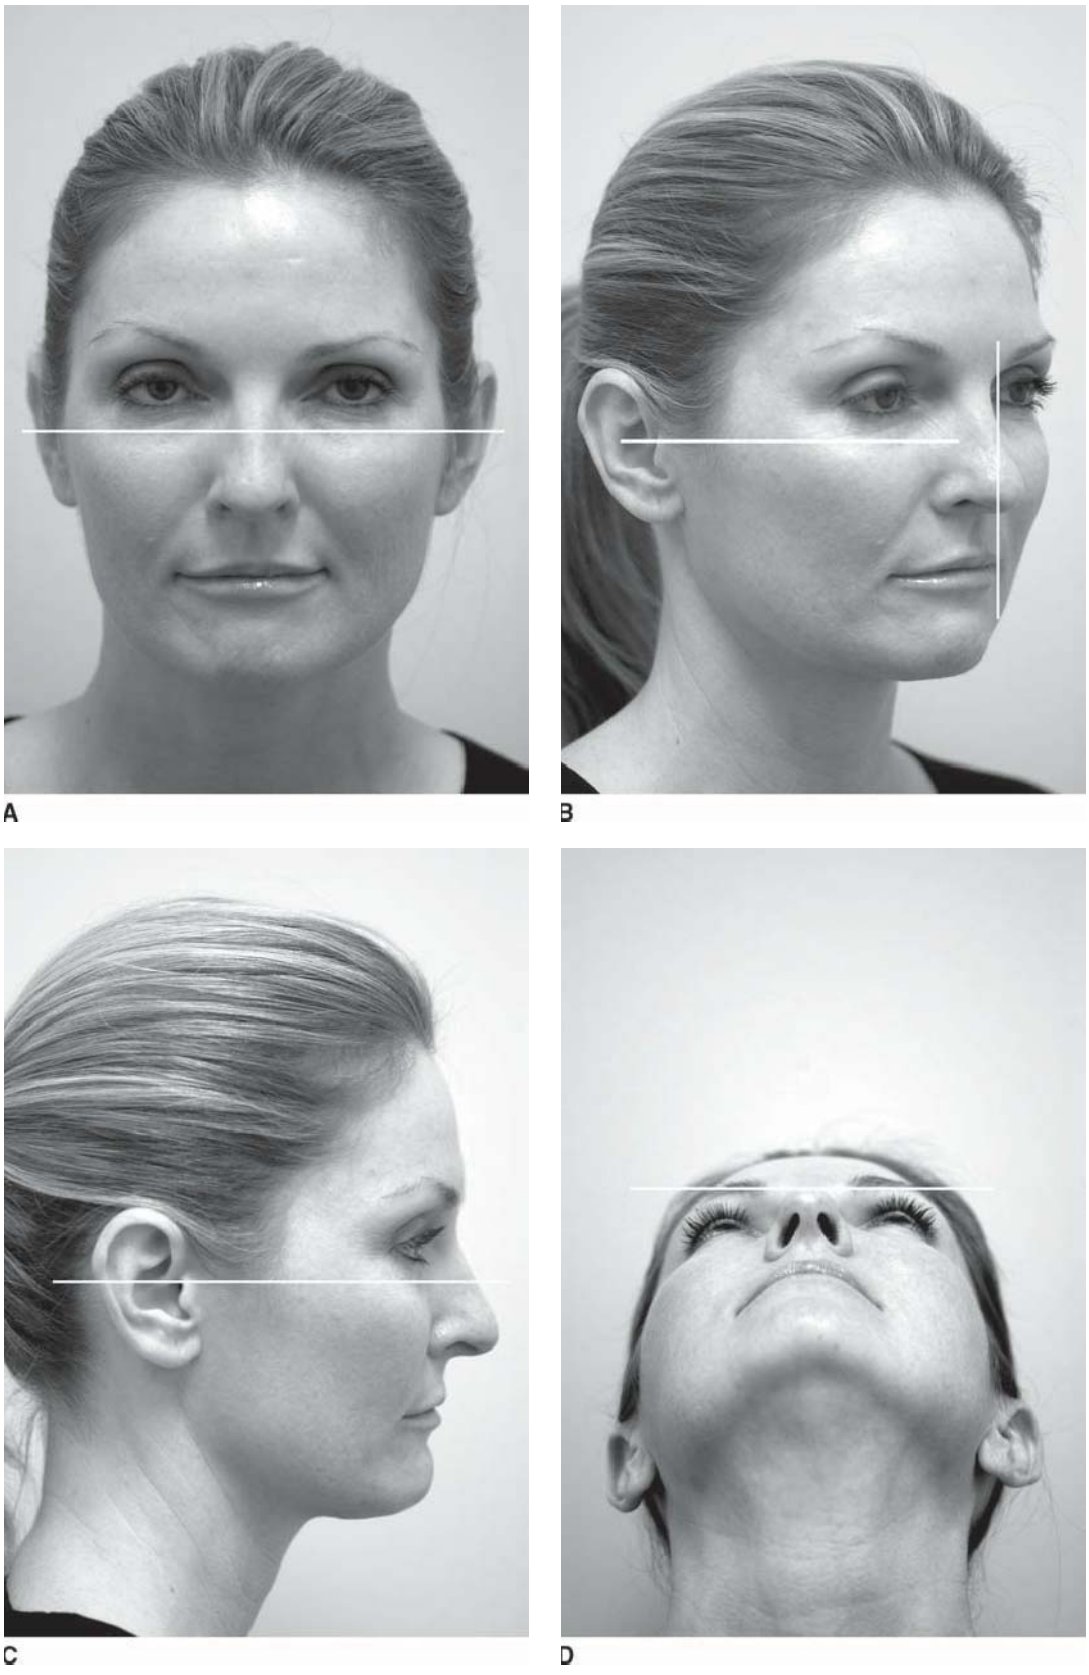

Figure 171.2 Standardized photographic views that show **(A)** frontal, **(B)** right oblique, **(C)** right lateral, and **(D)** basal of the patient. The *horizontal line* drawn in A–C indicates the Frankfort Horizontal Plane that runs through the supratragal point and the inferior orbital rim, which should be respected. The *horizontal line* in D shows the alignment of the nasal tip with the *infrabrow line.* The *vertical line* in B shows the alignment of the nasal tip with the malar eminence.

addition to distortion of the neck, over- or underrotation of the neck can cause the nose to appear erroneously rotated or derotated, respectively, and would compromise any photography for rhinoplasty (Fig. 171.3). Patients may also reflexively attempt to lift their brow if they have significant brow ptosis, making the pre- and postoperative result for browlift or upper blepharoplasty less meaningful. If the patient exhibits this behavior, the photographer should ask that the patient close his or her eyes forcefully and slowly open them until they appear fully open. This maneuver will help break the unwitting contribution of the frontalis muscle. The patient may also instinctively smile when posing for a photograph, so the photographer should gently remind the patient that no facial expression should be displayed.

Each type of planned surgical procedure mandates a different set of standardized positions with or without additional optional views (Table 171.1) (1). Besides patient positioning, distracting elements from jewelry, makeup, clothing, and hairstyling should also be minimized. All obstructive jewelry, for example, necklaces and pendulous earrings, should be removed. Turtlenecks and high-necked collars can also obstruct a straightforward view of the neck and should be pulled down or folded inward to enhance effective communication. All eyeglasses should be removed regardless of what facial surgery is being contemplated. Hairstyling ideally should be pulled back to show an unobstructed view of the eyes, nose, ears, lips, and neck and to be reduced to an unobtrusive element. Shorter hairstyles that do not interfere with any of the major facial features and the neck can be left alone or swept behind the helix of the ear as needed. All makeup should be removed, especially if any dermatologic resurfacing or scar revision is planned.

Lighting and Background

Lighting is also a critical element that should be standardized. Ambient lighting can be used alone or combined with fill lights or flash strobes. If the ambient lighting is too strong and casts a heavy shadow over the patient's facial features, then balanced fill lighting can be used to soften these harsh shadows. Hot lights positioned at

A B

Figure 171.3 Poor patient positioning is shown with the neck overrotated and extended that leads to distortion of the neck as well as for the nose, as seen from the frontal view (**A**) and from the profile view (**B**).

TABLE 171.1 RECOMMENDED, STANDARDIZED PHOTOGRAPHIC VIEWS FOR SPECIFIC FACIAL PROCEDURES

Procedure	Standardized Views
Botulinum toxin (Botox)	Frontal; frontal smiling: frontal frowning: frontal brow elevation (All photographs are taken before the first session regardless of what areas will be treated in order to enhance patient dialogue should the patient complain as well as to reduce the need for further photography if the patient desires other areas treated during future sessions.)
Rhinoplasty	Frontal; basal; L/R oblique; L/R lateral; +/− dorsal (head tilted down for a crooked nose) +/− smiling laterally (If the patient has an active depressor septi muscle that alters the nasal tip position during animation.)
Blepharoplasty/browlift	Frontal; L/R oblique; L/R lateral; closeup (May also take with eyes closed and upward gaze.)
Rhytidectomy	Frontal; L/R oblique; L/R lateral
Otoplasty	Frontal; L/R oblique; L/R lateral; posterior; R/L lateral closeup (Remember to tie long hair back in a bun and/or wear a headband to lift away obstructing hair.)
Malar augmentation	Frontal; L/R oblique; L/R lateral; basal
Hair transplant	Frontal; L/R oblique; L/R lateral; posterior; posterior with head tilted back; frontal with head tilted down +/− closeup of anterior/lateral hairline (When photographing the hair, the hair should be styled in a standardized fashion and "combovers" eliminated.)
Lip augmentation	Frontal; L/R oblique; L/R lateral; closeup mouth (Remember to remove lipstick, lip liners, and other makeup that can interfere with reproducible photography.)
Scar revision	Frontal; L/R oblique; L/R lateral; closeup (Consider reducing the exposure value to highlight the scar.)

45 degrees in front on both sides of the patient can be further softened by aiming the lights away toward reflective umbrellas. A "kicker" light placed behind the patient can fill in any remaining shadows cast by the two forward placed 45-degree lamps and slaved to go off when the camera's shutter is depressed (Fig. 171.4). Placing the patient an appropriate distance away (~2 feet) from the rear wall can also minimize unwanted shadows. Generally, an on-camera flash tends to cause excessive highlights and shadows and a "washed-out" appearance to skin tones, but experimentation will determine the best balance of lighting for a particular room and camera. Rather than use fill lights or strobes, the ambient lighting and the camera's aperture/exposure can be adjusted to achieve the desired lighting objective. Furthermore, the ambient room lighting can be altered to match the color spectrum (e.g., daylight balanced) of the film used or the settings of the camera so that, for example, a green cast from fluorescent lights may be avoided. If shadows and highlights are desired in order to accentuate a scar or other contour irregularity, for example, prominent nasolabial lines for correction with a soft tissue filler, then the balanced fill lights (if used) should be turned off. In addition, the exposure value can be reduced in order to draw out the intended feature. Obviously, the same settings should be used for the postoperative views.

The background should also be uniform and light in color. Ideally, a powder blue background is preferred. Too dark a background can swallow the facial features and should be avoided. Rather than hanging a blue drape behind the patient, a smooth wall can be painted the desired blue, as a wall will remain flat and wrinkle free. Again, using the exact same room with the same lighting will aid in achieving reproducible results. Conversely, carrying a portable blue background material from room to room to photograph the patient will most likely lead to subtle, if not obvious, inconsistencies in the photography. If a wall is to be painted blue, it may be wise to record the exact shade of blue, or corresponding numeric code, so that if the physician should have to relocate the photography room in the future the same blue color can be precisely reproduced.

Intraoperative Photography

Although good pre- and postoperative photography remains the core of this section, proper techniques for superior intraoperative photography should be mentioned herein. Intraoperative photographs can be used to document medicolegally what transpired in the operating theater but primarily serve as an educational tool for other training surgeons or as part of a didactic presentation in a

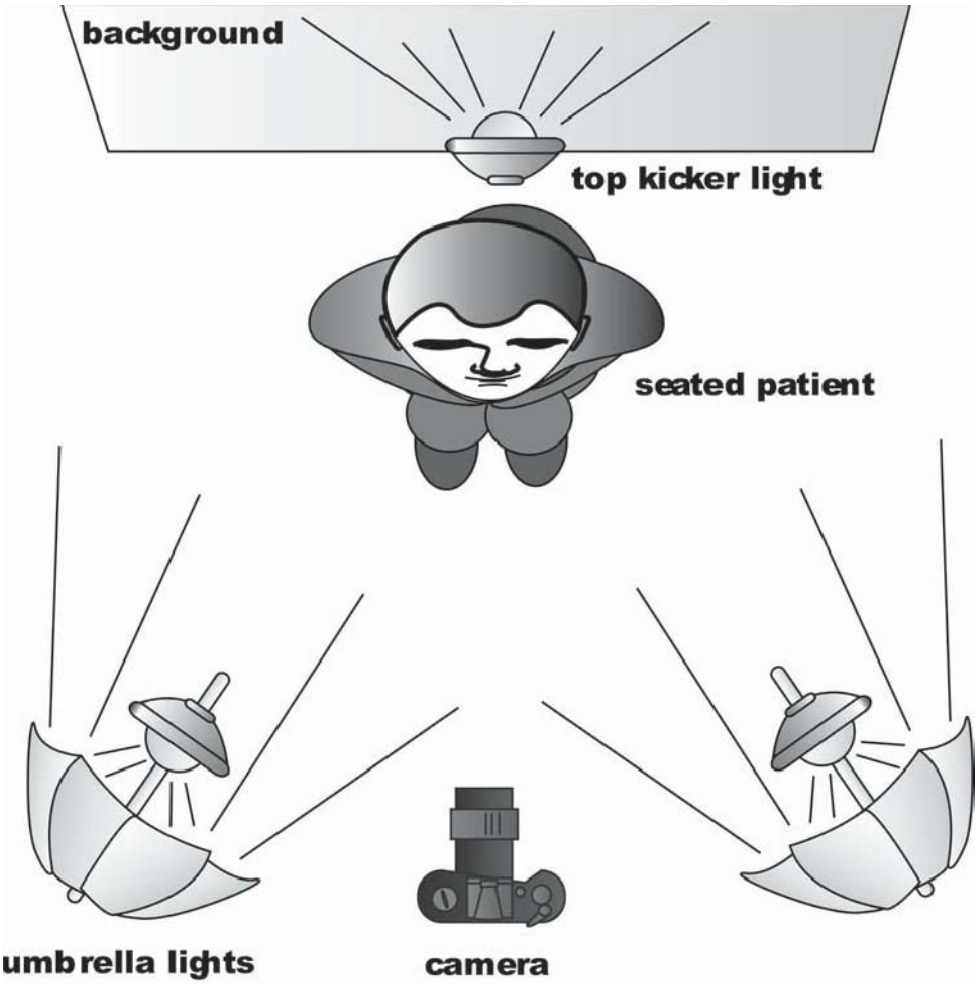

Figure 171.4 Standardized lighting is very important for good photography. If the ambient lighting is insufficient or casts very harsh shadows, fill lights can be used to soften the shadows. Ideally, two lights placed at 45-degree angles in front of the patient can be softened with the use of reflective umbrellas, and a "kicker" light that illuminates the background positioned above and behind the patient. These lights can be triggered to strobe as a slave unit when the camera's shutter is depressed or remain constantly on to be turned off after the photographic session is over.

scientific forum. A few basic techniques that have evolved from practical experience should be mentioned to help the surgeon achieve excellent results.

First, when taking any intraoperative photograph, care should be exercised to remove all bloodstains both on the patient's tissues and on the surgeon's gloves, as these elements that may appear inconspicuous through the lens become glaringly obtrusive when the final photograph is viewed. If sequential photographs are taken to document the stepwise approach to a procedure, the same angle should be maintained to enhance the clarity of communication. If a removed specimen is to be photographed, a ruler should be placed adjacent to it in order to provide dimensional understanding of the specimen. A metallic ruler can often cast a glare and obscure the legibility of the measurements: instead, a black ruler with white measurement markings minimizes glare and is ideal, albeit possibly difficult to procure.

Although a ring flash mount may provide uniform intraoral or other facial illumination, another method may serve as a better option. The intraoperative room lights are turned off and only two dedicated overhead, directional lights are positioned at 45-degree angles to the specific facial feature that the surgeon wants to highlight. The camera is set to spot meter off of the subject so that the surrounding background fades to a uniform black. The wrinkled blue background of a surgical gown or other drape held behind the subject always looks unprofessional and distracting. The described technique should be practiced with a particular camera's settings until the correct exposure is established (2).

TRADITIONAL PHOTOGRAPHY

Traditional, 35-mm film photography remains the "gold standard" by which the quality of digital photography is judged, though digital single lens reflex (SLR) photography offers many new advantages. Advantages of digital photography include ability to crop and adjust on a computer, instantaneous pictures, and easy storage and filing of images. The following section will discuss the various equipment needs for digital and 35-mm photography: many of the components discussed for 35-mm photography also apply to digital imaging, as camera body and lens designs for digital imaging have often been based on original 35-mm models.

Camera

Camera models can be divided into two basic types: point-and-shoot and SLR. Point-and-shoot cameras typically have the lens and body sold as one compact unit and are convenient for nonprofessional purposes like vacation photographs where portability is a priority. SLR cameras are higher-end models that usually consist only of the camera body with the lens (which can be interchanged with lenses of other focal lengths as needed) sold separately. Besides higher production quality that is characteristically associated with an SLR camera, this kind of camera also benefits from the absence of parallax error. An SLR camera avoids this distortion because the image seen through the viewfinder exactly matches what the film plate will be exposed to, as a mirror that transmits the image through the lens to the viewfinder is displaced to expose the film plate when the shutter is depressed.

With the rise of digital products, prices for 35-mm SLR cameras have plummeted. Nevertheless, many of the very advanced features that appear on an SLR camera are excessive for clinical photography, for example, high rate of frames taken per second, manual controls, etc. A basic SLR camera body that will accommodate high-quality lenses is sufficient for clinical usage.

Basic Photographic Concepts

In order to take consistently good standard photographs that will allow you to document the nuances of the human facial anatomy, an understanding to basic photography is required. One important concept is the DOF. This is the distance range in which the relevant portions of the image are in sharp focus. The focal point is the point in the image that appears sharpest. For example, if the point of interest is the nose, with the appropriate DOF, everything including the ears would be in focus on frontal view. In this case, the nose would be the focal point and therefore have the sharpest focus within the DOF. Having the correct DOF is important during facial photographic documentation. Digital SLR cameras allow manipulation of the DOF by changing three variables: the focal length of lens, the aperture size, and the distance of the subject to the photographer.

The shorter the focal length of the lens, the larger the DOF. Point-and-shoot cameras exploit this property in order to keep everything in focus. This inverse relationship between the focal length and DOF is important when using digital SLR cameras, as interchanging lenses with different focal lengths can be used to modify DOF. In some cases, distortion can occur with change in focal length; therefore, changing focal length to enhance DOF is not always ideal.

Unlike the inverse relationship between DOF and focal length, the distance between the photographer and the subject directly effects the DOF. At any given focal length, objects that are imaged at long distances will be seen with greater DOF. Space constraints in most studios often limit this possibility.

Of the three variables, the ideal way to increase the DOF is by manipulation of the aperture size (3). The DOF varies inversely with the aperture size. Aperture size is measured in f-stops, which is a value based on a calculation of the ratio of the focal length of the lens to aperture diameter in millimeters. Therefore, an f-stop of f/16 is a smaller aperture size than an f-stop of f/4. In other words, an aperture f/16 provides a greater DOF than an f-stop of f/4. With each increase in f-stop, the aperture area is roughly halved, and the DOF is therefore increased.

When changing aperture size to improve DOF, it is important to realize that exposure will be affected by changes in the aperture size (3). Increasing the DOF by increasing the f-stop will result in less light entering the camera. To maintain the correct photographic exposure when the f-stop is increased, two factors can be manipulated. The first factor is the sensitivity of the medium used to light. In 35-mm film cameras, this was measured with the American Standards Association (ASA) or International Organization for Standardization (ISO) scale. The greater the sensitivity of the medium to light, the higher the ISO (3). Digital SLR cameras have the ability to alter the ISO value. With digital SLR cameras, to maintain the correct photographic exposure when the f-stop is increased, the shutter speed needs to be reduced to prevent underexposure. Shutter speeds range from 1/60 to 1/1,000 of a second. Therefore, if increasing the f-stop is performed to increase the DOF, the shutter speed should be reduced as well.

For clinical purposes, the following basic guidelines are suggested for managing the camera settings. Four basic types of settings exist for most advanced SLR cameras: automatic, aperture priority, shutter priority, and manual. Automatic mode functions by allowing the camera's onboard computer to decide both aperture and shutter speeds. The lack of control using this setting may result in variability. Manual mode allows absolute photographic control but can be burdensome and yield poorly exposed photographs in less than professional hands. Aperture priority (A mode) allows the photographer to adjust the aperture setting while the camera's onboard computer automatically alters the shutter speed to achieve the ideal exposure given the ambient conditions; shutter priority (S mode) allows the converse, that is, control of the shutter speed, while the computer adjusts the aperture automatically. Clinically, aperture priority is the preferred mode, which ensures the appropriate exposure while achieving the best DOF. The smaller the aperture (that correlates with a higher numeric "f"-stop) yields greater DOF. It is helpful to experiment with the different aperture settings to determine the ideal DOF without excessively long shutter speeds, which can in turn lead to camera shake and a resultant blurred photographic image.

Lenses

A high-quality lens that attaches to an SLR camera is the most important element to attain distortion-free, high-quality photographs. Whether shooting with 35-mm film or digital SLR, the lens can be used interchangeably between the two systems. A reputable manufacturer, for example, Nikon or Cannon, is a reliable indicator of lens quality. Lenses are characterized based on the focal length, which is defined as the distance in millimeters from the optical center of the lens to the focal point, which is located on the film or camera sensor if the subject is in focus. The field of view (FOV) is determined by the angle of view from the lens out to the scene and can be measured either vertically or horizontally. Thirty-five-millimeter SLR cameras use larger sensors or films in order to capture a wider FOV. The FOV that is associated with a focal length is usually based on 35-mm photography. For example, in 35-mm photography, lenses with a focal length of 50 mm are called normal as they work without magnification or reduction. Lenses with a short focal length function as wide angle lenses and therefore capture more because they have a wider picture angle. Conversely, lenses with long focal length function as telephoto lenses and have a narrow picture angle.

Digital cameras on the other hand, capture images on sensors called charged coupled devices (CCDs), which are smaller than 35-mm camera frames (3). As a result, the smaller CCD sensor captures only the central portion of the information projected by the lens. This results in a cropped FOV and is the same effect as using a lens with a longer focal length (e.g., telephoto). The correction factor for the difference in size of the sensor to the traditional 35-mm window is called the focal length multiplier (FLM). This is an important concept to understand as it explains why the same lens will take different looking photos on a 35-mm SLR camera body versus a digital SLR. Specifically, at the same focal length, the digital SLR can produce a distortion of the midface (fish-eye look) as a result of the FLM. With digital SLR cameras, the FLM refers to the effective lengthening of the focal length and is equal to the diagonal of the 35-mm film (43.3 mm) divided by the diagonal of the sensor. In the example of Nikon digital SLR cameras, the FLM is 1.5, and therefore, a lens with a focal length of 60 mm would be equivalent to a 90-mm SLR lens when fitted on a digital Nikon SLR. For pictorial documentation, it is critical to use a lens that produces the least distortion and provides the largest DOF to ensure that the entire face is in focus. Macro lenses between 90 and 105 mm meet these criteria for 35-mm SLR cameras, and macro 60 mm meet these criteria for digital SLR cameras. Although a better DOF is provided by lenses with shorter focal lengths, the facial anatomy distortion becomes significant.

For 35-mm film portrait photography, a 105-mm macro lens will provide photographic images without shape distortion like a disproportionately magnified nose and reduced ears in a fish-eye look that may be present with other focal lengths. For digital photography, a 60-mm macro lens will provide the optimal photographic image for facial photography.

Data Back

An optional feature that may be worth purchasing for an SLR-type camera body is a data back, which usually replaces the hinged door on the back side of the camera used for film exchange. The data back provides the capacity of recording time and date onto the exposed film, which may serve as a useful tool for memory recall, photographic organization, and legal documentation. Digital cameras, on the other hand, do not require this feature, as the time, date, and other information are recorded with each image automatically.

Viewfinder Grid

The standard unmarked viewfinder can be replaced in many camera models with one that has vertical and horizontal markings on it. These marks help guide the photographer when following the guidelines enumerated in Figure 171.1 for good photography, for example, the Frankfort Horizontal Plane, aligning the inner canthus to the outer oral commissure on the oblique view, etc. (Electronic, on-demand grids come equipped on some high-end digital camera models that replicate this feature.)

Tripod

Speaking of camera shake, a tripod upon which a camera can be mounted promotes a stable platform for portrait photography. For intraoperative usage, setting up and using a tripod can be overly taxing and also violate sterile surgical field. If a tripod is to be used for portrait photography, several tripod features are worth acquiring. A quick-release feature on the tripod head permits the camera to be rapidly removed and taken free hand as needed. An easily adjustable tripod neck that allows rotation of the camera to achieve horizontal and vertical framing is also an important feature. Finally, wheels that can be mounted to the base of the tripod afford easy maneuverability so that the tripod can be positioned without having to lift and relocate it.

Film

Although traditional film-based photography may be divided into 35-mm, medium-, and large-format film types, 35 mm has remained the mainstay of practical clinical photography with the latter two types relegated to nonmedical, artistic endeavors. Thirty-five-millimeter film may be purchased either as negative or transparency (reversal) stock. Generally, the latter has been preferred for

several reasons. Slide film produces accurate skin tones, is relatively inexpensive, is easy to project for scientific and patient communication, requires little storage space, and can have good archival preservation. Generally, if sufficient lighting is present, then a fine-grain film like 25 or 64 speed film is preferred for the high quality of the image and reproducibility of that quality when enlarged (4). If the physician prefers to remain in a film-based medium, it would be advised to consider using a digital camera or a Polaroid for immediate feedback and to ensure that the necessary image has been obtained. Also, use of a digital camera and/or Polaroid facilitates immediate patient dialogue that would otherwise be deferred due to processing time of slide film.

DIGITAL IMAGE MANAGEMENT

A few years ago, digital photography was in a nascent stage of development, and chapters described digital imaging only briefly as a tentative alternative. Today, digital photography has continued to make rapid technologic strides and has challenged 35-mm photography for its many benefits: no consumable costs of film, instant image feedback, capacity for digital morphing, no physical storage space, no processing time or expense, and easy reproducibility and backup. Nevertheless, the initial setup cost for digital photography can be quite high due to the associated hardware requirements, for example, computer, cables, software, storage, etc. Today, most offices already use computers, so few additional hardware expenditure is typically required. Moreover, the cost of technology is rapidly tumbling, and the lack of consumables will offset initial outlay very rapidly, unless every photograph is printed, for instance, on expensive inkjet paper. The primary criticism leveled against digital photography in the past concerned the purported dubious image quality as compared with the "gold standard" of 35-mm film. However, that argument is truly obsolete with the rise of 12 megapixel cameras and beyond. No accurate comparison can be made between a digital pixel and the silver-halide grain of film, but this argument really borders on arcane academic banter and lacks any practical clinical import. This section discusses input devices (digital cameras and scanners [to convert 35-mm images over to digital]), image processing and storage (compression, archiving, and morphing), and output devices (printers and projectors) (5).

Input Devices

Cameras

Like 35-mm film cameras, digital cameras may be broadly classified as point-and-shoot and SLR-type models (Fig. 171.5). Due to an SLR digital camera's expense, many consumers purchase a point-and-shoot digital model. Like 35-mm cameras, an SLR digital camera can offer higher image quality and flexibility. Oftentimes, an SLR digital model will accommodate traditional 35-mm lenses, which can greatly save expense for the owner of these same lenses. Obviously, a high-quality, aspherical lens achieves commensurate value as in 35-mm photography. However, unlike traditional 35-mm film photography, the digital camera body contributes significantly to image quality, in terms of pixel resolution, color variation, dynamic range (i.e., the ability to capture the broad spectrum of bright whites to dark blacks), and light sensitivity. For these reasons, as mentioned for SLR cameras, it is imperative that the same digital camera and lens (not to mention the same lighting and studio) be used to attain consistent photographic results. Unlike 35-mm film in which a 105-mm macro-type lens provides a distortion-free image in portrait photography, various lenses may provide a true 1:1 image for a particular digital camera based on the size of the CCD or CMOS (complementary metal-oxide semiconductor),

A

B

Figure 171.5 Like 35-mm cameras, digital cameras can be classified as point-and-shoot **(A)** and as SLR models **(B)**. Unlike 35-mm photography, the digital camera body can be as important as the quality of the lens in obtaining superlative photographic results. In general, digital SLR models have better build-out quality, but the prospective consumer should always evaluate objective reviews before any purchase.

which would be analogous to the 35-mm film plate. As reviewed above, the prospective consumer should ask the manufacturer of the SLR digital camera, which focal-length lens will provide a distortion-free 1:1 image for that specific camera model. As a general example, the 60-mm Cannon macro lens on a Cannon SLR body will achieve distortion-free photos comparable to the 105-mm macro/35-mm SLR combination. Since film is not used, ISO or ASA ratings that describe the light sensitivity of a particular film stock are not applicable for digital cameras. Nevertheless, as most consumers are familiar with what an ISO/ASA rating means, some digital cameras have adopted this terminology to describe the light sensitivity of a CCD/CMOS, with standard digital models having an ISO rating of between 50 and 200 and higher-end cameras over 400. DOF can also be different for a specific "f"-stop, as compared with a traditional 35-mm setup. Generally, a smaller numeric "f"-stop (i.e., wider aperture) will yield a greater DOF than in a 35-mm equivalent. Despite these differences, many of the principles outlined for good photography and basic equipment parallel those discussed for 35-mm photography.

Scanners

Scanners are used to convert a 35-mm library or select printed images into the digital medium. There are basically two types: flatbed and film scanners. The former consists of a specialized camera housed below a clear glass panel with a hard, opaque cover that scans an image in a linear fashion to convert it into a digital version. The flatbed scanner benefits from versatility (ability to scan multiple media, like photographs, tables, graphs, text, and—with the right adapter—even transparency or negative film) and economy (a relatively low cost). Film scanners are dedicated to scanning only slides or negatives and can do so often very quickly and at a higher resolution. Unfortunately, they also tend to cost considerably more in price. Sophisticated image correction software to repair damaged and faded slides are also featured in some high-end film scanners, like with the Nikon's series of film scanners.

Four parameters define a scanner's ultimate output quality: optical resolution, bit depth, color accuracy, and optical density (OD). Optical resolution simply refers to the number of pixels per inch (ppi) and can be achieved by a straightforward pixel per pixel output or manipulated by a process known as interpolation, which can prove to be inferior. Most scanners offer an optical resolution between 300 to 4,800 ppi and an interpolated resolution of 0 to 1,900 ppi. Generally, 300-ppi scanning is sufficient for printed materials, whereas a 72-ppi resolution is adequate for web or monitor display. Bit depth refers to the maximum number of colors that each pixel of an image can display. This numeric value is expressed as the exponential power of 2. For instance, a 1-bit image has two colors (2^1) like black and white. Although most monitors only output 24-bit images (i.e., 2^{24}, or 16.7 million colors), scanners can exceed this value and be 30, 36, or even 42 bits. However, these higher bits are not superfluous, but the added data undergo a selection process for the best bits of color information to yield a 24-bit output product. Color accuracy refers to the scanner's ability to reproduce faithfully the original photographic image's colors. The International Color Consortium measures this accuracy with the "Delta E" value. Good Delta E values fall below 10, whereas poorer figures exceed 30. Finally, the OD usually is only a descriptor on higher-end models and denotes the brightness that a scanner can capture. OD is expressed in a logarithmic fashion so that a scanner with a 3.6 D (or OD) will have 10 times the brightness of 1 with a mere 2.8 D. If a scanner does not list an OD, the rating probably falls between 2.8 and 3.0. It is recommended to have a minimum of 3.2 D for transparencies and 3.4 D for negatives.

Image Retrieval, Storage, and Morphing

Compression

Compression refers to the mathematical algorithm used to reduce an image's overall size and therefore necessary memory allocation. Although there are many competing compression formats, the two most popular and relevant for clinical utility are TIFF (Tagged Image File Format) and JPEG (Joint Photographic Experts Group). TIFF represents a "lossless" compression, in which there is no loss in image resolution after the image is compressed. Unfortunately, due to the smaller compression ratio (typically 2:1 or 3:1), file sizes can be quite large on the order of several megabytes. JPEG images are "lossy" images that lose some quality (usually undetectable to the human eye) when compressed with reduction in file size from 10:1 to 300:1. Clearly, the more the file is compressed, the greater the loss in quality. Interestingly, every time a JPEG image is cropped or altered in any way then saved, additional loss of image quality is incurred. If the image will be manipulated numerous times, it may be wise to work from a TIFF image then convert to JPEG on the final edit.

Editing and Morphing

One of the complaints about digital imaging concerns the ability to "doctor" or alter an image unethically. This charge is a bit misguided because 35-mm film can also be digitally altered and returned to its original format. Further, some editing software like Canfield Scientific's Mirror system has built-in authentication process to detect altered images. What constitutes ethical editing? Color balancing and fine adjustment of hues and brightness, just as if you had sent film to a processing laboratory, should be considered proper. Further, cropping extraneous elements in an image so long as the image integrity has not been undermined should be deemed acceptable as well. These powerful tools underscore the strengths of the digital

format. Intentional editing, or morphing, allows alteration of a digital image so that the surgeon can communicate with the patient an intended aesthetic result. Care should be taken to avoid overpromising and to remind the patient of the shortcomings in accuracy of a digitally morphed image. Morphing can be particularly effective when demonstrating to a patient the change in nasal profile and/or change in the neck and chin region for two principal reasons. First, the patient rarely if ever sees himself or herself from the side view. Second, the soft tissues are contrasted against a blue background, making image alterations relatively straightforward (as compared with moving skin over skin in a frontal view).

Archiving

The lack of physical space that a digital library takes up is also an undeniable benefit. However, the physician would be wise to select a good archiving program early so that the growing catalog of digital images can be easily organized and subsequently retrieved. There are two basic types of archiving software: browser and catalog. Browser-type software permits simple retrieval of graphic images and is usually bundled free with purchased digital cameras. On the other hand, catalog software often permits more sophisticated handling of many file types (text, graphic, video, and audio) and can attach metadata to a file. Metadata refers to the descriptive text that can be attached to a file to facilitate its retrieval, for example, "Susan Smith," "Crooked Nose," etc. It is often easier to maintain the alphanumeric name that a camera assigns to an image, for example, DSC_1789.jpg, and simply attach descriptive metadata to it. When organizing patient's images in a hierarchical folder, placement of the year, followed by the month, then the day, for example, 2005-11-6 for November 6, 2005, is preferred so that chronologic order is maintained.

Storage

Digital imaging permits infinite backup without the considerable expense associated with copying film transparencies or negatives. Backing up data should occur on a daily or weekly basis, and data should be stored both on premises and off site to ensure maximal protection. Many options exist for data storage including magnetic drives, magnetic–optical drives, optical drives, tape drives, and hard drives. Generally, tape and magnetic media are preferred for large storage backups, whereas optical media are better suited for smaller file-to-file storage.

Output Devices

Printers

Three principal types of printers exist for photographic reproduction: inkjet, dye-sublimation, and color laser. Inkjet printers comprise the majority of printer sales and can provide high-quality print resolution. They function by spraying small amounts of ink onto the paper in halftones that are layered on top of one another. Parameters that define a high-quality printer are as follows: printer resolution expressed in dots per inch (dpi) with a good printer having upward of 1,440 dpi; the number of color inkwells (3 being a relatively low number and 6 being a favorable number); and the size of the ink droplets (3 to 4 pL are superior to 6 to 18 pL). Lightfastness refers to the printer's capacity to produce an image that retains color and avoids unfavorable color shifts over time, with some recent models being able to exceed 100 years in lightfastness. Dye-sublimation printers, or dye-subs, work by depositing vaporized ink lifted from a colored ribbon onto a specialized paper to achieve a more continuous-toned print. Unfortunately, these printers are more expensive and can only print a predetermined size, for example, 5 × 7 or 8 × 10 inch. Paper costs can also exceed that of quality inkjet paper. Color laser printers can produce high-quality images at a faster rate than inkjet printers. In addition, consumable costs can be lower, and machines are more durable. However, initial cost outlay for a laser printer can be considerably higher than a standard inkjet. Office volume and cost expenditure will dictate which printer is best suited for the job. The one major limitation that still faces the conversion of on-screen to printed digital images concerns color correction. Many digital images are created in RGB (red–green–blue) mode that is native to computer monitors. However, printers work in CMYK (cyan, magenta, yellow, and black [the "key" color]) mode. The translation from one color scheme to another can cause some color mismatch. Details for color correction lie beyond the scope of this chapter.

Projectors

Scientific, marketing, and business conferences have attested to the advent of the digital revolution: increasingly, digital projectors are preferred to traditional slide projectors for effective communication. The ability to embed animation and video footage during a digital presentation has made the digital format an unquestionably superior medium of communication. The different types of projectors that are available today include cathode ray tubes (CRTs), liquid crystal displays (LCDs), digital light projectors (DLPs), and plasma display panels. CRT projectors deliver a strictly analog signal, as compared with all of the other aforementioned types. Despite this fact, some proponents of CRTs argue that they provide as good if not superior image quality to their digital counterparts. LCD projectors may be divided into higher quality Polysilicon types and standard active-matrix styles. DLPs rely on micromirrors and have been cited to produce brighter images and have superior video capacity. However, LCDs have been thought of having better color contrast and saturation. Plasma screens work by combining pixels with CRT phosphors.

Several specific parameters should be sought when evaluating a projector's utility. Clearly, portability is important

for someone seeking this option. Native resolution comes in VGA (640 × 480), SVGA (800 × 600), XGA (1,024 × 768), SXGA (1,280 × 1,024), and UXGA (1,600 × 1,200). CRTs do not have a native resolution and are deemed resolution independent, which means that they do not need to be matched to a monitor's resolution. Conversely, digital projectors should be matched to a monitor's resolution as precisely as possible. If several computers are intended for use with one projector, then the projector should be matched to the computer monitor with the highest resolution. A minimum of an SVGA projector should be acquired for straightforward graphic presentations, but an SXGA is preferable. A projector's brightness is measured in ANSI lumens with a minimum of 300 to 500 ANSI recommended for dimly lit rooms and 1,000 ANSI for a well-lit room. For an auditorium, at least 1,500 ANSI should be sought. The contrast ratio that describes the range of brightest whites to darkest blacks is also a valuable feature with a range of 100:1 (low) to 2,000:1 (high). Zoom lenses permit image size adjustment without the burden of having to move the unit. Digital keystone correction adjusts the image to reduce distortions that arise from aiming the projector at the wall from an angle. Lamp life can range from 40 to 40,000 hours, with the majority falling between 1,000 and 2,000 hours. Lamp replacement can be expensive so this factor should also be integrated into the choice of a projector.

CLOSING THOUGHTS AND THE FUTURE

Good photographic principles should be adhered to whether working in 35-mm or digital photography. Photographic documentation should always be obtained in any cosmetic or reconstructive endeavor but may also serve as a reliable tool for other types of head and neck surgical procedures on an individual case-by-case basis. The rise of digital photography has transformed the landscape of scientific and professional communication. As technology continues to evolve, digital photography will most likely entirely supplant analog 35-mm film. The next edition of this chapter will probably bear the short title "Pictorial Documentation: Digital Imaging."

172 Grafts and Implants in Facial, Head, and Neck Surgery

G. Richard Holt *Christian L. Stallworth*

The biotechnology of implants in otolaryngology and head and neck surgery has expanded rapidly, and facial, head, and neck implants now include autologous biomaterials, metals, polymers, synthetics, and tissue-engineered materials. Since the range of requirements for implants ranges from bone replacement and stabilization implants to soft tissue fillers, the science of surgical implantology now involves cell surface physics, molecular level biochemistry, and tissue engineering. Biomaterials, both biologic and synthetics, for osseous and soft tissue augmentation are becoming increasingly important in reconstructing defects of traumatic, congenital, extirpative, and aging etiologies.

BIOCOMPATIBILITY OF IMPLANTS

Cells do not adhere directly to the surface of implanted synthetic materials. A substance in the extracellular matrix binds the cell to the surface. This substance is essential for initial cell adhesion and proliferation. The substrate needed varies with the type of cell. Well-differentiated cells, such as chondroblasts, osteoblasts, and epithelial cells, require substrate characteristics distinct from those needed by less differentiated cells, such as fibroblasts. Focal contacts represent adhesion sites to specific extracellular matrix proteins adsorbed on the implant surface. Focal contacts typically occur in low-motility cells, such as fibroblasts and epithelial cells. The composition of the substrate (the adsorbed layer of protein on the implant surface) is crucial for tight cellular adhesion. Proteins such as fibronectin, vitronectin, cold-insoluble globulin, and possibly proteoglycans provide the necessary substrate for this adhesion.

The extracellular matrix contains collagen, elastin, and fibronectin interwoven into a hydrated network of glycosaminoglycan chains. The glycosaminoglycan chains are long, negatively charged polysaccharide chains that link proteins to form giant proteoglycan molecules. Interaction with cell membrane receptors provides linkage for cellular attachment to adsorbed extracellular matrix on the surface of a biomaterial. Tissue cells do adhere to the implant surface—not directly but by means of a complex series of protein attachments.

When implants are placed in facial soft tissue, the primary tissue reaction includes protein adsorption and cellular attachment. The predominant cell attaching to the protein layer is the fibroblast. Within the first week, the fibroblast lays down immature collagen on the implant surface, or interstices. The usual response to a soft tissue implant is production of a fibrous capsule or collagen fiber ingrowth, which secures the implant. A smooth implant such as silicone more often elicits dense capsule formation than does a porous implant. If an implant is too reactive, has surface contamination, or is biodegradable, the host tissue response usually is aggressive macrophage activity, increased vascularity, breakdown of the overlying skin, and extrusion of the implant. The presence of inflammatory cells such as neutrophils and macrophages suggests poor tissue response to the implanted material.

After placement of an implant, protein adsorption occurs. As a hole is drilled into bone to receive the implant, the bone must not be heated to more than 45°C to 50°C, or osteoblasts die. An implant in bone induces a rapid host response. The first stage is formation of a small hematoma and a cascade of chemical breakdown products. These substances act on blood vessels and attract cells from surrounding tissue. Because cortical bone is avascular, most blood products come from the marrow-containing spaces of the bone.

The second stage is tissue organization, regeneration, and repair. The duration is related to the extent of injury and implantation site geometry. Extracellular processes and cell functioning can be affected by soluble and insoluble particles from the implant and by the mechanical influence of the implant itself. The third stage of repair is

remodeling, which affects the implant–host tissue interface and occurs over weeks or months. Appropriate stress levels must be imposed on the bone adjacent to the implant. Bone-binding intensity can be measured according to the shear or torque forces needed to produce failure. Bone is the main contributor to tensile strength of bonding; other tissues are less important. The basal lamina in contact with a bone implant contains type IV collagen, laminin, and proteoglycans. These constituents of the ground substance are deposited in or adjacent to the mineralized layer. Mineralization of the ground substance seems to be important for transmission of compression and for shear and tensile loads.

CHARACTERISTICS OF IMPLANTS

Implant material is characterized by composition, strength, biodegradability, and resistance to stress and fatigue (1,2). The properties of bulk material, however, can differ from those of the implant surface at the tissue–implant interface because of surface alterations by design or physicochemical reaction. The materials and clinical applications for facial, head, and neck implants are summarized in Table 172.1.

Metallic Implants

Metallic devices can be composed of a single metal or an alloy of several metals. Alloys are developed to improve qualities of the original metal by adding other metals with characteristics that improve biocompatibility or mechanical attributes. The principal metals used in facial implants are titanium, stainless steel, and tantalum. Chromium, aluminum, cobalt, copper, nickel, and tungsten are included in alloys.

Metals are crystalline materials with well-defined, orderly, three-dimensional arrangements of atoms that form a microscopic lattice characteristic of each metal. The lattice can be modified by means of heating, cooling, hardening, or altering the physical properties of the metal to achieve a particular result. Lattice defects can modify the characteristics of the metal. Large structural defects can cause failure to withstand external stresses. Metallic biomaterials are characterized by elastic modulus, tensile strength, percentage elongation, compressive strength, shear strength and modulus, and strain. Stress is the ability of a material to withstand a given load per cross-sectional area. The material must be designed to meet the functional requirements of the dental or maxillofacial implant.

TABLE 172.1 FACIAL, HEAD, AND NECK IMPLANTS

Category	Biomaterial	Clinical Application
Metals and metallic alloys	Stainless steel	Sutures, fracture wires, reconstruction bars
	Titanium and its alloys	Mandibular bone trays, osseointegrated implants, cranioplasty, orbital floor implants
	Platinum–iridium	Implantable electrodes
	Gold	Eyelid implant
Polymers	PMMA	Cranioplasty, tissue adhesive
	Cyanoacrylate	Tissue adhesive
	Silicone elastomers	Soft tissue augmentation, tissue expanders
	PTFE	Joint prosthesis covering, vocal cord injections
	ePTFA	Soft tissue augmentation, orbital floor implant
	Polyurethane	Artificial skin
	Dacron, nylon polyesters	Sutures, onlay mesh, mandibular trays
	High-density polyethylene, porous	Soft tissue augmentation, temporomandibular prosthesis
Ceramics	Bioglass	Middle ear ossicular replacement
	Hydroxylapatite	Joint prosthesis covering, bone-conduction filler, bone augmentation
	Aluminum oxide	Cranioplasty, artificial ocular prostheses
Nonceramics	HAC	Bone filler, cranioplasty, bone conduction
Biologic materials	Polyglycolic acid	Sutures, implants
	Polylactic acid	Timed-release drug delivery, implants
	Collagen	Dermal augmentation, soft tissue support
	Bone-stimulation proteins	Cartilage or bone induction
	Hyaluronic acid	Soft tissue filler
	Human acellular dermis	Soft tissue filler, augmentation

Stress versus strain curves are generated experimentally for implant materials. They provide information about the bulk material independent of shape or thickness. These can be used to predict the response of the material to mechanical forces on an implant in a particular use. The forces of shear, compression, tension, torsion, and bending must be considered in selection of a material for an implant. *In vitro* loading studies are performed to assess how a material responds to long-term wear. Most metals relax with time, and the relaxation can cause metal fatigue and implant failure. A relatively brittle metal, such as stainless steel, can function well initially but with long-term use can fail because of fatigue. All metals corrode when exposed to living tissue; the gradual result is failure of many metal implants. Stainless steel, an alloy of iron, chromium, nickel, molybdenum, and manganese, resists corrosion well. It can, however, undergo gradual plastic deformation.

Titanium and its alloys are among the most biocompatible metallic implants used today. Titanium is lightweight and corrosion resistant and has high tissue acceptance. It is rather soft and when not anchored to bone can be deformed by loading forces. Used in mandibular reconstruction and for anchoring screws in facial applications, titanium performs well. Tantalum and vanadium have been used as bone trays for mandibular reconstruction, but the mechanical properties are not as good as those of titanium. Tantalum and vanadium are not strong, can fatigue rapidly, and must be removed after the mandible heals. Some metallic implants, such as stainless steel, have a better stress response than does bone. This can cause stress shielding of the bone and impede formation of new bone. Metal implants may have to be removed after the bone is stabilized to allow growth and development.

Ceramics

Ceramics have a microscopic lattice structure. Glass ceramics, on the other hand, have an amorphous atomic structure. Most biologic implants are glass ceramics—combinations of silicon dioxide (SiO_2) and crystalline lattice materials embedded in this glass. Glass ceramics are thermally resistant and can be used when thermal shock can occur. Glass ceramics last well in the body. They are well tolerated and biocompatible. Because of a peculiar grain size and distribution, however, glass ceramics are susceptible to cracking from stress concentration. Clinically, these are considered brittle materials; they fracture rather than bend when subjected to excessive stress. This limits the use of glass ceramic implants in the head and neck to areas with minimal force loading, such as a tympanic ossicle.

Ceramics made with alumina compounds also are used in dental implants. The device is designed so the shape facilitates biomechanical stress application without fracture. Hydroxylapatite is another form of ceramic; it is characterized as bioreactive. It comes as a powder and is reconstituted as a paste for dental and bone replacement. Hydroxylapatite is resorbable and osteoconductive, and it increases bone density. It is composed of elements that exist in the ground substance of bone, that is, calcium and phosphorus. Hydroxylapatite can provide a substrate for osseointegration and osseoconduction when used as a bone replacement material for facial, head, and neck defects.

Facial augmentation with calcium hydroxylapatite (Radiesse, Merz USA, Greensboro, NC) microspheres in a gel carrier of carboxymethylcellulose can provide soft tissue enhancement for a correction period of 12 to 18 months when injected subdermally. Because the hydroxylapatite microsphere is in a gel suspension, the material can be massaged after injection into the tissues to create a smooth appearance (3). When used in porous granular form for facial skeleton augmentation, the material has been found to maintain its bony skeletal projection for at least 2 years (4).

Polymers

No synthetic implant material can exactly reproduce the biomechanical properties of bone. Ceramics and metals are stronger than human bone, and polymers are more flexible. Polymers are useful in implantation because the mechanical properties can be altered to suit the application. These properties are derived from the structural and chemical composition, which are related to length and cross-linking. Varying these two characteristics can produce a wide range of polymer properties, from soft and fragile to hard and brittle. The implant designer can choose a polymer that provides the characteristics needed for a particular situation.

The most commonly used medical polymers are polyurethanes, silicones, and polymethyl methacrylate (PMMA). These polymers are reasonably strong and biocompatible. When supplied as porous fibers (polytetrafluoroethylene [PTFE], nylon, polylactic acid, and polyglycolic acid), these materials can be woven fabric as well as suture material. Expanded PTFE (ePTFA) fabric (Gore-Tex, Gore Medical Co., Flagstaff, AZ) has excellent biocompatibility when used for soft tissue augmentation or vascular repair. Mechanical stresses on polymer implants usually are small. When used for mandibular replacement, a polymer is tested for the same mechanical tolerances as are metals, including tensile strength, modulus of elasticity, stress, and strain. Impact testing is important when a material is used for skull reconstruction. Internal defects that occur during molding and processing can cause cracks and implant failure.

Polymers are manufactured by means of thermoplastic molding (the material is formed in a heat-softened state in a mold) or by means of thermosetting (the insoluble polymers are cured by cross-linking). Suture material is formed by means of extrusion of the polymer through small holes in a die to produce a fiber thinned to the proper diameter

before cooling. Used as a glue, PMMA, ethyl-2-cyanoacrylate, and butyl-2-cyanoacrylate produce histotoxic cellular reactions and an exothermic reaction. A permanent injectable polymer of cleaned microspheres of PMMA suspended in bovine collagen (ArteFill, Suneva Medical, San Diego, CA) is FDA approved for augmentation of the nasolabial folds. Serious complications such as granuloma formation have not been reported with this synthetic injectable, allegedly owing to the minimalization of the number of microspheres smaller than 20 μm (5).

Polydioxanone (PDS) is a resorbable material utilized in suture material and in thin sheets for support of osseous defects, usually an orbital wall fracture. Recently, PDS foil (PDS Flexible Plate, Mentor, San Diego, CA) has been utilized to support nasal cartilaginous structures during septoplasty and rhinoplasty, which can be particularly useful because of its low extrusion rate, structural strength during healing, and ability to support multiple free fragments of septal cartilage as a scaffold for reimplantation (6,7).

Biologic Materials

Grafts of nonhuman biologic material and xenografts are considered implants because they often are used for tissue augmentation. Bovine collagen in injectable solution or sheets (Zyderm, Allergan Medical, Irvine, CA) is enzymatically modified to diminish cutaneous sensitivity reactions and to decrease resorption time. When the macrophage system of the host identifies this collagen as foreign, immunologic defenses form antibodies to the collagen. Because collagen is similar in many ways among species, this problem can be diminished but not eliminated with biochemical alteration of unique proteins. Synthesis of components of human dermal collagen and basement membrane, such as polyglycolic acid and polylactic acid, has produced suture and implant material that is slowly resorbed by means of acid hydrolysis. These materials do not induce the intense immunologic response of animal collagen. They also are used as the carriers of sustained-release drugs in implantable drug delivery systems.

Human acellular dermis matrix, harvested from cadavers, is utilized primarily as a soft tissue augmentation material for the face. It can also serve as a "filler" or "scaffolding" for repair of a nasal septal perforation, where this material is placed between opposing flaps of nasal mucosa; if exposed, it allows for reepithelialization on its surface. Foreign antigenicity of this human allograft is achieved by leaching out the cells; however, there are "ghost channels" of preexisting vascular structures that may serve to support revascularization of the tissue. There is a tendency of this biomaterial to resorb with time in some patients.

Biodegradable (resorbable) plates and screws are not dissimilar to certain biodegradable suture materials. These firm implants are generally composed of biosynthetic polymers and copolymers of polylactide and polyglycolide and are heat malleable to fit the contour of the bony surface. They should be especially considered in pediatric fracture patients, where metallic plates can cause stress shielding and loss of bone growth and remodeling capabilities. Such minimally invasive bioabsorbable bone plates are being increasingly utilized in facial skeleton fractures, and they have been shown to be as strong as a titanium plate when fixating fractures of the mandibular body (8). A so-called "interflex" design allows for decreasing the volume of the plate while still maintaining a low stiffness and an absorption rate that allows for gradual reduction of mechanical stability commensurate with a gradual increase in load bearing of the healing mandible.

Patient-Specific Implants

With the growing availability of three-dimensional radiographic computer modeling, surgeons can preoperatively analyze bony and soft tissue defects through virtual manipulation. This can even be done for existing defects, but also prospectively to forecast a defect that will result from an ablative procedure. With this technology comes the ability to fabricate *patient-specific implants* (PSIs). Using the patient's native contralateral anatomy or gender- and age-specific norms, implants can be constructed to replace tissue loss in multiple dimensions. Examples include preoperative fabrication of mandibular reconstruction plates to be used following composite resection of the mandible or multidimensional implants needed to replace a complex midface defect resulting from maxillectomy. In this way, manufactures are able to tailor their implant materials to precisely restore unique, patient-specific defects.

Polyetheretherketone (PEEK) (Synthes Craniomaxillofacial, West Chester, PA) is a semicrystalline polyaromatic linear polymer that is inert, nonporous, and customizable. More than 20 years of reliable use in the aerospace, automotive, and electrical industries led to its ultimate use as substitute for bone grafting and titanium cages in the treatment of cervical disc disease. PEEK has proven biocompatible, strong, and stable. It has the benefits of bone-like stiffness, can be secured with plates and screws, is lightweight, and can withstand the sterilization process. It also holds the advantage of customization (9,10). With computer modeling, a PSI can be manufactured. Digital renderings and a tangible model of the patient's skull and the fabricated implant are then provided to the surgeon for manipulation and approval preoperatively.

ASSESSMENT OF PATIENT NEEDS

As with all reconstructive procedures, it is imperative to evaluate each patient's individual needs, the goals for reconstruction, and whether or not an implant will be needed to achieve these goals. Before an implant is used, a patient's general operative candidacy must be considered. Patients with severe cardiopulmonary or other systemic diseases may be poor candidates for general anesthesia, especially if

multiple stages will be required. In these cases, single-stage procedures done under monitored local anesthesia may be in the patient's best interest. The recipient's wound-healing potential and immunologic status are also assessed. Patients with diabetes, hypertension, microvascular disease, and malnutrition; those who smoke; and patients undergoing chemotherapy, radiation therapy, or taking immunosuppressive drugs are all at risk of impaired or delayed wound healing, possible infection, and eventual implant extrusion. A history of sensitivity to any component of the implant must also be sought. A thorough history and physical exam can help forecast these pitfalls and help the surgeon plan accordingly.

Once patient fitness has been established, focus turns to characteristics of the recipient site. Form and function lost at the recipient site help guide selection of an implant appropriate for the defect and compatible with the patient. Salient points include the soft, bony, or composite character of the tissue defect; the native function of the tissues lost; and their interaction with surrounding tissues. The need to bear a load, to withstand friction or other conformational stress or strain forces, or to stand up during specific activity for the patient are additional factors to consider in choosing an implant. When a young adult applies for a facial, head, or neck implant, the physician must ask about the person's usual physical activity level and sports participation. A common cause of implant loss is trauma, which causes hematoma formation, loosening of the implant, and extrusion. Patients must agree not to participate in contact sports or to delay implantation until the questionable activity is no longer a consideration.

Implants are typically used to manage bony or soft tissue defects caused by birth defects, trauma, or tumor resection. In the case of congenital defects, surrounding tissues are typical naïve and healthy, posing less risk to the implant. This is not true in many cases of traumatic or ablative defects. Traumatized tissues may have been subjected to thermal and mechanical injury that has altered surrounding tissue cellular architecture, vascularity, and pliability. Any previous infection at the site must also be considered. In the case of malignancies, patients typically have undergone some combination of surgical, radiation, and/or chemotherapies that each may adversely affect tissue viability and ultimate implant stability. Most patients with a history of irradiation of the proposed recipient sites are not good candidates for implants unless distant, nonirradiated tissues can be brought into the area. This often necessitates procedures with several stages and perioperative hyperbaric oxygen therapy for best results. Similarly, if further radiation therapy is planned after implantation, the surgeon should recognize that use of metallic implants may pose difficulties in dosimetry. In the management of deformities attributable to ablative cancer surgery, it often is prudent to delay prosthetic implantation as long as 1 year after surgery. The patient is observed for an extended period after implantation for the development of residual or recurrent disease and for rejection of the implant.

When a patient or their defects are not ideal for restoration with an implant, a prosthesis may be the ideal option. Even in these cases, though, prosthesis fixation must be considered. Fixation can be categorized as mechanical (use of a facial accessory like eyeglasses), anatomic (relying on natural facial contours for prosthesis retention), and adhesive (glues, magnets, or osseointegrated abutments). With respect to osseointegrated implants, three main factors impact retention—bone volume, local hygiene, and a history of radiation exposure to the surrounding tissue. Extraoral, skin-penetrating abutments have a long track record for successful nasal, orbital, and auricular prosthesis fixation (11).

For osseous replacement or augmentation implants, radiologic assessment of the recipient area is advisable. At minimum, computed tomography (CT) is needed. Three-dimensional CT has also become more widely available and can be linked to a computer-aided design (CAD) and fabrication system for precise manufacturing of the prosthesis. Magnetic resonance imaging is not as helpful for evaluation of osseous deformities as it is for soft tissue assessment.

Finally, the difference between functional and cosmetic implants should be noted. A functional implant is chosen to provide the best restoration and the lowest risk of complications. In cosmetic applications, emotional and psychological development is considered as well. The condition of the recipient tissues is likely to be the limiting factor in functional cases, and psychological factors count heavily in cosmetic implantation.

SURGICAL MANAGEMENT

Preoperative Counseling

It is imperative for the surgeon to discuss the risks and complications associated with alloplastic and biologic implantation with each surgical candidate. Foremost among these are infection, rejection, and extrusion of the implant. If the preoperative history and exam identify host factors that may have a deleterious effect on healing and thereby increase these risks, these must be shared with the patient (Box 172.1). In addition, patients may have personal or religious beliefs that influence their willingness to accept use of an alloplastic material, an allograft, or a xenograft. A surgeon must discuss the patient's overall surgical candidacy, the potential need for multiple reconstructive stages, and the balance of aesthetic versus functional goals, all in hopes of setting reasonable expectations regarding outcome. The authors advise against showing photographs of patients who have undergone implantation because each case is unique. Rough drawings or photographs of the patient that have undergone computerized facial analysis are helpful as long as the patient understands that there is no expressed or implied guarantee of success.

BOX 172.1 HOST FACTORS THAT MAY POSE THREAT TO IMPLANT SUCCESS

Cardiovascular disease
Diabetes mellitus
Smoking
Alcohol abuse
Impaired immunity
Poor nutrition
Advanced age
Immature skeletal age
Prior radiation at site of implantation
Prior trauma or surgery at site of implantation
Inadequate bone or soft tissue volume

Surgical Implantation

Each region of the face, head, and neck requires an implant with unique properties. The ideal implant does not exist, but some possess many of the following qualities thought to be important:

Biocompatibility with host tissue
Noncarcinogenic nature
Simulation of the biomechanical features of the tissue it augments
Easy fabrication
Capability of being sterilized without degradation of essential properties
Capability of being resorbed or lack thereof depending on the tissue needs
Thorough investigation before use

Each region is reviewed herein, but the specific surgical techniques are found elsewhere in this book and the medical literature. Table 172.2 summarizes site-specific selection of surgical implants.

Scalp

Little has been done in the development of scalp implants. Most scalp surgery is performed for hair replacement, and grafts or flaps are used. Autologous hair follicle unit implants are commonly used both for posttraumatic defects and for genetic baldness. Over the years, the size of the follicular grafts has decreased, and microfollicular grafts, from 1 to 5 follicular units, are now used allowing for better camouflage and filling in of the defect.

Silicone tissue expanders work well in the sustained expansion of skin for reconstruction after scalp loss.

TABLE 172.2 SURGICAL IMPLANTS BY SITE

Site	Biomaterial	Clinical Application
Scalp	Silicone	Tissue expansion
Skull	Silicone, titanium tantalum, hydroxylapatite, PMMA	Cranioplasty
Ear	Silicone	Electrode covering
	Titanium	Osseointegrated implants
	Platinum–iridium	Cochlear electrodes
	Porous polyethylene	Auricular reconstruction
Orbit	Titanium	Osseointegrated implants
	Silicone hydroxylapatite, PTFE, ePTFA	Orbital volume
	Polycarbonate	Intraocular lens, artificial eye
	Methylcellular fiber silicone	Orbital floor fractures
Face	ePTFA; carbon PTFE; porous, high-density polyethylene; polyamide; hydroxylapatite	Soft tissue and osseous augmentation
	Collagen	Dermal augmentation
	Human acellular dermis	Dermal augmentation
	Calcium-based hydroxylapatite	Soft tissue filler
	Hyaluronic acid derivatives	Soft tissue filler
Mandible	Dacron polyester, nylon, titanium alloy, tantalum alloy	Reconstruction tray
	Stainless steel	Reconstruction bar
	Titanium alloy	Miniplates and screws for trauma
	Titanium	Osseointegrated implants
	Silicone	Temporomandibular meniscus
	Hydroxylapatite	Bone conduction
	Silicone, ePTFA, carbon PTFE, porous high-density polyethylene, polyamide	Mentoplasty
Neck	ePTFA	Vascular grafts and sutures
	Polyglycolic acid, polyglactin 910, polypropylene, stainless steel	Wound closure

Expansion of the generally inelastic scalp requires 6 to 8 weeks to obtain a sufficient amount of expansion, depending on the size of the defect. Large, non–hair-bearing scalp defects can be excised, and expanded hair-bearing scalp can be advanced/rotated into the deficit. Attention must be given to hair growth direction and to maintaining the appropriate anterior hairline. It should also be noted that follicular density decreases in the expanded scalp skin.

Skull

Cranioplasty with allopathic implants is one of the oldest head and neck procedures. PMMA, a common cranial implant, is formed from several monomers in the presence of a catalyst and can be molded to the defect before hardening (12). It can be drilled, sculpted, and secured to the surrounding bone. Its polymerization is exothermic, and the implant is sterile on hardening. Alloys of titanium and tantalum are available in plate or mesh-sheet form and can be cut or bent as necessary. Because they deform slowly with external trauma, malleable metal implants for skull defects are likely to protect the brain, unlike PMMA, which is brittle and can fracture with trauma.

Hydroxylapatite cement (HAC) can also be utilized for cranioplasty defects, especially in children (13). Small defects can be molded in place, utilizing fast-setting HAC. For larger defects, computer-aided design/computer-assisted manufacturing (CAD/CAM) of a larger HAC (or PMMA) can be preformed and placed into the defect with little alteration.

Ear and Temporal Bone

Reconstruction for microtia has primarily utilized rib cartilage; it is easily accessible, can be carved and sculpted, has been shown to grow with the patient, and is an autologous biomaterial. There is a slight risk of pneumothorax, hypertrophic scar, or keloid formation, and harvest may not be properly placed in females where breast development has not yet occurred. Additionally, multiple stages are generally required to achieve a good result. However, rib cartilage remains the gold standard for microtia repair.

Preformed porous polyethylene implants (Medpor, Stryker CMF, Newnan, GA) are utilized by some surgeons for a one- or two-stage ear reconstruction. This polymer implant must be covered by a temporoparietal fascial flap, and the flap, in turn, covered by a thin, full-thickness skin graft. The immediate result is good, but the risk of complications is higher than with the rib graft—loss of the fascial flap, breakdown of the skin graft, hypertrophic scar of the scalp, and potential trauma caused by the firmness of the implant. Because the implant does not grow with the patient, sizing at an early age is problematic.

Prosthetic ears are also a viable option for ear reconstruction, particularly in the case of auriculectomy from an ablative procedure. Like other regions in the head and face, the best choice for prosthetic attachment involves implantation of pure titanium fixtures into bone. In fact, the mastoid process has the most ideal bone volume for implant integration and retention (11). These fixtures osseointegrate fully with bone before loading (14). They are attached to skin-penetrating abutments and linked with a gold bridgework that contains attachment magnets for the prosthesis. Similar implants can be used to anchor a hearing aid to the temporal bone for better sound transmission than is offered by a conventional bone-conduction hearing aid, particularly in congenital canal atresia and in postsurgical chronic tympanomastoiditis where a canal-dwelling ear piece causes recurrent drainage.

In cases of conductive hearing loss, partial and total ossicular replacement prostheses may be used in middle ear reconstruction. Any number of stapes prostheses are also available for treatment of otosclerosis. For treatment of sensorineural hearing loss, cochlear implants containing an array of stimulation electrodes inserted in the cochlea may be used. They are made of platinum and iridium, two rare metals with high electrical conductance and minimal rectification at the electrode–tissue interface. They usually are coated with PTFE or silicone to diminish current loss into the tissues and to protect the electrode from corrosion.

Orbit

A diverse number of implants are frequently used for the repair of the orbital floor and lateral walls following trauma. For small fractures, thin sheets of methyl cellulose, such as Gelfilm, can be stacked and placed over the defect to serve as temporary support until scar tissue has formed and they are resorbed. Some surgeons use silicone sheets to support the orbital floor after an orbital blow-out fracture. The biocompatibility of this material is excellent, and if properly placed and sized, the implant has a low extrusion rate. Severe fractures of the orbital floor can be repaired with a size-altering titanium implant. The device is trimmed to the required size and is adjusted by means of bending to the required anatomic defect. The implant can be fixed to the orbital rim with self-tapping screws. Porous polyethylene preformed implants can also be utilized as a support for the orbital floor, either placed acutely or in a delayed reconstruction of a hypo/enophthalmic orbit. It is possible to carve some of the polyethylene implant to fit the topography of the orbital defect. Hybrid implants made from titanium mesh coated in porous polyethylene can also be used to restore larger orbital floor and wall defects.

Mesh implants made of polyglactin 910 can be used as a slowly resorbable replacement of the orbital floor. Soft tissue pads (1 to 2 mm thick) made of ePTFE fabric can be used to repair posttraumatic hypophthalmos and for temporal augmentation. The rate of infection is low, the foreign body reaction is minimal, and there is good incorporation into the tissues (15). This material is soft and pliable and easily contoured to the size and shape of the defect. Polyglactin 910 sutures (Vicryl Plus, Ethicon, Inc., Menlo Park, CA) can secure the implant to the medial and lateral orbit.

In the enophthalmic orbit following trauma, orbital volume can be restored with bone grafts or with inert substances such as PTFE, silicone beads and sheeting, Medpor (Stryker Corp, Newnan, GA), hydroxylapatite, or ePTFE fabric. Symmetric placement of the expanders, in consultation with an ophthalmologist, can diminish postoperative diplopia. Following orbital exenteration, osseointegrated implants have been used to successfully anchor orbital prostheses (Fig. 172.1). As noted previously, bone implants for patients who have undergone irradiation are less successful unless hyperbaric oxygen therapy is used. In the case of enucleation, artificial globe implants manufactured from new polymers such as polycarbonates can be designed and painted for a near-perfect match with the other eye. Intraocular lens implants also can be made of a polymer fabricated with a specific fixed focal length for patients who have undergone cataract extraction.

Gold and platinum weights are used successfully for rehabilitation of patients with facial paralysis. Use of weights can replace tarsorrhaphy in many cases. These rare metals are inert in tissue and well tolerated in the thin upper eyelid. Sutured anterior to the tarsus, a gold weight provides reversible surgical lowering of the eyelid (16). The proper weight is selected preoperatively from a "dummy" weight-sizing kit. The patient sits, and weights of varying sizes are taped to the eyelid until the desired lid position is achieved. The weight is sterilized and inserted under local anesthesia. It serves the purpose to help initiate a relaxation of the superior levator muscle of the upper eyelid and to add to the gravitational pull of the eyelid for closure.

Parel, MD, The University of Texas Health Science Center, San Antonio, TX.)

Midfacial Augmentation

Augmentation of the malar region, the premaxilla, and the nasal dorsum is sometimes wanted. Although many surgeons prefer to use autogenous tissue such as cartilage or bone, alloplastic materials are being used with increasing success. Surgeons variously favor mesh (e.g., polyglactin 910, polyamide, and polyester), silicone rubber, porous polyethylene, porous PTFE or vitreous carbon fibers or aluminum oxide particles combined with PTFE, ePTFA mesh, and hydroxylapatite. Each biomaterial has advantages and disadvantages related to fiber network, pore size, inflammatory response, and ability to be secured in place. HACs come in a thick paste form and can be molded and contoured as onlay grafts.

In a fabric framework, such as ePTFE, which has a small pore size, tissue ingrowth occurs uniformly. Because of the 1- to 2-mm thickness of ePTFE, the fibroblasts can completely penetrate its depth, which is not always possible with the thicker porous implants such as porous polyethylene MedPor (Stryker Corp, Newnan, GA). All of these materials can be cut and contoured to correct the defect (Fig. 172.2). Preformed ePTFE fabric chin and malar implants are available in addition to the facial augmentation sheets. Facial augmentation can also be performed safely with ePTFE fabric.

Although it is possible to place small implants subperiosteally, large, nonyielding implants placed beneath the periosteum can cause pressure resorption of the underlying bone. The use of alloplastic materials on the dorsum and tip of the nose is controversial. Hard silicone implants are used in Asia, but they have a high rate of extrusion. ePTFA fabric (Gortex, Gore Medical, Flagstaff, AZ) has been used successfully for augmentation of the tip and the dorsum

Figure 172.2 **A:** Woman with flattened left malar eminence after facial trauma. **B:** Rapid intraoperative expansion of tissue pocket to receive the implant. **C:** Layered ePTFE fabric implant is fitted to the left cheek. **D:** Augmented cheek 3 months after surgery.

of the nose. This graft seems to be easily tolerated by the thicker nasal dorsum tissues and, if secured to the periosteum, has a low rate of migration. It is soft and has a more "natural" feel than the more firm silicone. Human acellular dermis can be used as a nasal augmentation biomaterial, especially as a filler for defects when autologous cartilage is not readily available. There have been instances where it is totally resorbed, so one must be prepared for a second augmentation, should this occur. Successful immediate replacement of the alloplastic implant with autologous cartilage grafts has been reported and recommended (17).

In cases of complex bony defects of the midface, restoration of tissue volume in multiple dimensions can be challenging. For these reasons, preformed PSIs may be an ideal option for bony defects. PEEK implants fabricated with the help of three-dimensional imaging and virtual volume analysis provide a reconstructive option tailored to a patient's complex defect like that found following maxillectomy (10). If a prosthesis is the best option for a cosmetic defect, they may be anchored to underlying bone with osseointegrated implants. The growing success of endodontic implants has led some surgeons to use these for midface prosthetic fixation as well (11).

Perioral and Facial

It has become increasingly important to some patients to have perioral and facial wrinkles reduced and the lips made more plump. Facial plastic surgeons utilize a number of alloplastic and biologic materials to achieve these results. Human acellular dermis, ePTFA tubular implants, and autologous fat have been utilized for increasing the size and projection of the lips and to lessen the depth of the nasolabial folds. However, currently there is increasing use of injectable soft tissue fillers, rather than firm implants.

Fat injections, obtained from the submental region or abdomen, can also serve as a biologic filler for these areas. Some initial erythema and reaction may result from the breakdown of the fatty acids, but usually the autologous graft is well tolerated. There may be some resorption, based on technique of harvest, so overinflation is generally observed. Currently, many surgeons are beginning to investigate the use of autologous stem cell harvests from fat in order to restore soft tissue volume and enhance the longevity of results.

As collagen has presently been withdrawn from the US market (Zyplast & Cosmoplast, Allergan, Irvine, CA), newer soft tissue fillers have supplanted its use as an injectable filler for wrinkle reduction and soft tissue augmentation. Calcium hydroxylapatite–based injectable implant (Radiesse, Merz Aesthetics, San Mateo, CA) can be used in most facial wrinkles, especially perioral and glabellar lines. Immediate pain on injection and short-term erythema have been reported (18). Other fillers include various formulations of cross-linked hyaluronic acid (Juvederm, Allergan, Irvine, CA and Restylane & Perlane, Medicis Aesthetics, Scottsdale, AZ). Results vary, but in general, last for approximately 12 months. Although a cautious approach has been advocated in the widespread use of these filling agents, their use across multiple disciplines for treatment of the aging face has become widespread. The use of injectable filler materials for facial augmentation is discussed in greater detail in Chapter 197 of this text.

Mandible

The main source of bone for mandibular reconstruction is autogenous bone. Bone pate or larger grafts can be fashioned into carrier trays made of nylon, polyester, titanium, or tantalum to hold it in position. These trays are fabricated in the shape of the mandible and trimmed to resemble the missing segment. When the tray is filled with cancellous bone, new bone forms within it. The tray can be removed after sufficient bone has formed to withstand stress and load. Stainless steel or titanium reconstruction plates can be inserted after mandibulectomy to maintain spacing. These reconstruction bars are fixed with locking screws to the proximal and distal segments to minimize motion. They may be removed when a graft is placed. In some cases, the plate itself and a regional soft tissue/muscle flap are adequate to support the bone grafts (Fig. 172.3). Many mandibular reconstructions are performed using a free flap of bone and soft tissue, often including muscle, based on the mechanical requirements of the defect, and the feasibility of vascular anastomoses.

Repair of mandible and midface fractures has been improved with miniplating and microplating systems in which a titanium alloy and self-tapping screws are used. These plates can be left in place indefinitely except when the overlying skin is thin and the plates cause discomfort. These same screws and plates can be used to secure bone grafts and other implants to the facial bones. Resorbable fixation plates are becoming a more comfortable option for some surgeons—they are typically composed of biodegradable materials, mainly polymers and copolymers of polylactide and polyglycolide. They gradually lose their strength, enabling the underlying bone to begin to remodel with stress uptake. Their application is good in the pediatric patient, in uncomplicated mandibular fracture, in non–stress-bearing fracture locations (maxilla, frontal sinus, periorbit), and also in fixating suspension sutures (endoscopic brow lift). These resorbable plates can be heat bent to the proper shape required using a thin metallic template as a guide.

The technology of osseointegrated intraoral implants has revolutionized the dental profession. Patients who could not previously wear dentures can do so with Branemark implants solidly anchored to the jaws. A single tooth, a partial denture, or a complete denture can be anchored in place with these fixtures. Fixtures can anchor augmentation bone grafts to the jaws and can be placed in a mandible reconstructed completely from autogenous cancellous bone or from a vascularized radius bone.

Mentoplasty implants are made from a variety of biomaterials—polymers (solid, gel, or mesh), carbon or

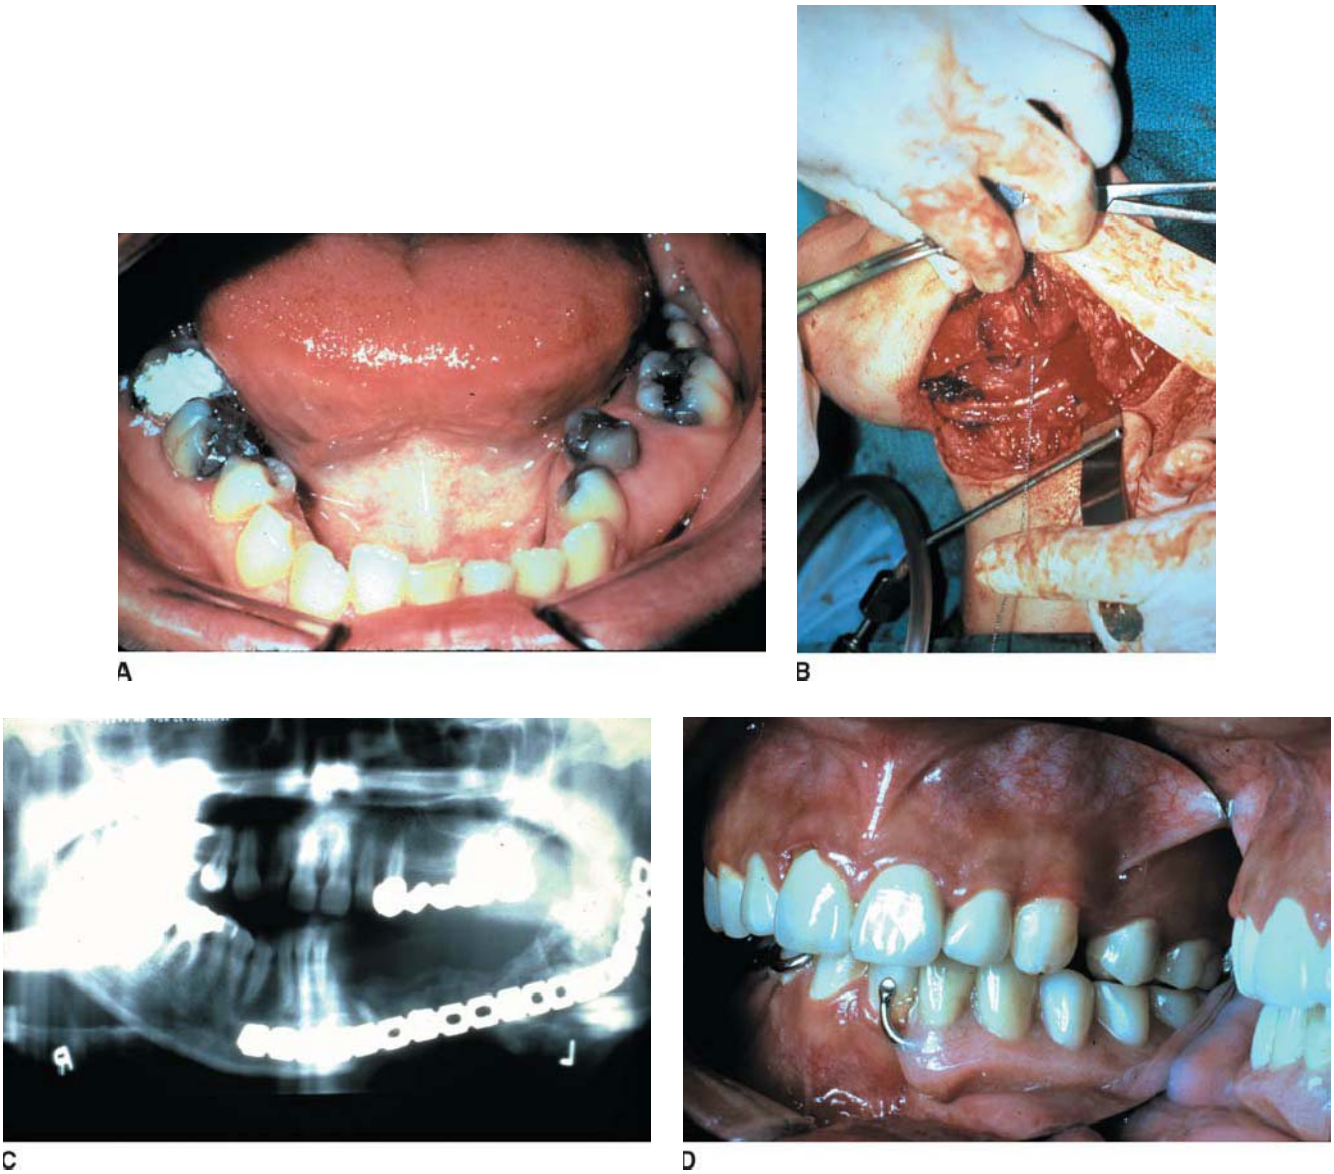

Figure 172.3 **A:** Preoperative view shows patient with chondrosarcoma of the left mandible. **B:** After resection of the mandible, immediate reconstruction was performed with a stainless steel reconstruction bar, autogenous iliac bone grafts, and a partial sternocleidomastoid muscle flap. **C:** Radiograph shows reconstruction bar and iliac bone grafts in place before removal. **D:** Intraoral view after removal of the reconstruction bar and healing of the mandibular grafts, with removable denture in place.

aluminum oxide combined with PTFE, high-density porous polyethylene, and ePTFE fabric. As with other sites of facial augmentation, the implants are best placed extraperiosteally and secured to the periosteum by sutures. Both extraoral and intraoral insertions can be used, and both approaches seem to work well when placed by an experienced surgeon. Most surgeons tend to anchor the implant in the midline and use subperiosteal pockets to insert and secure the lateral arms of the implant. Patient satisfaction with ePTFE chin implants has been reported as high as 97% (19).

Hydroxylapatite has been used as a bone-conduction material to provide a nonorganic framework for ingrowth of osteoactive cells to correct small defects of the mandible and maxilla. The success of this approach varies. In the future, the material may function better if combined with osseoinductive intervention. Several replacement prostheses for the temporomandibular joint have been investigated, but a single best biomaterial has not emerged. Silicone sheeting has been a reasonable substitute for the meniscus in the joint, but the articulating surfaces of most implant prostheses undergo wear and degradation.

Neck

In the field of phonosurgery, a number of laryngeal implants have been used for vocal fold medialization and

augmentation. Historically, Teflon injections were used, but proved unpredictable, irreversible, and found to incite significant, long-lasting host inflammatory responses. In its place, hyaluronic acid, calcium hydroxylapatite, and autologous fat are now commonly used for injection augmentation. Medialization laryngoplasty is also performed via a thyroplasty approach. ePTFE ribbon, silicone Montgomery stents (Boston Medical Products, Westborough, MA), and surgeon-carved Silastic implants may each be used depending on surgeon preference and patient candidacy.

In vascular surgery, the use of ePTFE patches has improved the results of carotid artery surgery for stenosis, primarily because of excellent biocompatibility with the hematogenous cellular and clotting factors and because it functions as a substrate for endothelial ingrowth. Suture material for closure of neck wounds includes synthetic biosorbable sutures such as polylactic acid or polyglactin 910; ePTFE vascular sutures; stainless steel skin staples; or polypropylene sutures, which also are hemocompatible for vascular repair. Use of these materials has decreased the incidence of wound breakdown and bleeding.

Following laryngectomy, the silicone tracheoesophageal fistula prosthesis is a removable implant in the neck that has excellent surface properties in contact with aerodigestive tract secretions. A certain amount of fatigue and degradation occurs with this functional implant, and it must be replaced frequently. Use of tracheostomy tubes composed of highly surface-biocompatible silicone and PTFE with low-pressure polymer sheeting balloons have greatly reduced the complications of tracheal erosion and blockage of the tube lumen.

COMPLICATIONS AND EMERGENCIES

Bleeding, infection, traumatic injury to the implant, implant mobility, and extrusion are the primary complications of surgical implantation in the face, head, and neck. Malposition of the implant, unacceptable cosmesis or functional restoration, overcorrection or undercorrection of the defect, host inflammatory reactions, incitement of a viral flare, inappropriate selection of implant material, and overall patient dissatisfaction also affect outcome. These complications usually can be prevented through careful pairing of both patient and implant, preoperative counseling, meticulous surgical technique, and close follow-up evaluation.

Infection is a primary concern with any alloplastic implant and is a common reason for implant failure and need for removal. Most surgeons use perioperative antibiotic therapy, and all use aseptic surgical discipline. It is essential to prevent contamination of the implant before insertion. Sclafani et al. explain that risk of alloplast infection and rejection is primarily increased when bacterial contamination is present at the time of implantation and/or prior to fibrovascular tissue ingrowth. In order to prevent infection, surgeons have used a number of varied and typically unproven preimplantation techniques. These have included saline rinses, antibiotic immersions, and povidone-iodine (Betadine, Purdue Products LP, Stamford, CT) irrigations (20). Keefe and Keefe demonstrated that suction infiltration of an antibiotic solution at the time of implantation provides a statistically significant advantage to infection prophylaxis, particularly in materials with a smaller pore size. Floating or immersion techniques alone provided no inhibition to bacterial growth (21). Incorporation of antiseptic agents into the biomaterials can also minimize the risk of infection. If the implant site does become infected, high doses of broad-spectrum antibiotics are prescribed, and hot compresses are applied. Impending extrusion or failure to control an infection necessitates immediate removal of the implant.

Some liquid implants have produced histotoxic effects or hypersensitivity reactions. Ethyl-2-cyanoacrylate, a short-chain cyanoacrylate derivative, activates severe cellular toxicity, but butyl-2-cyanoacrylate, a longer-chain derivative, has minimal histotoxic effects. If it is necessary to use a tissue glue for adhesion of one hard tissue to another, butyl-2-cranoacrylate is the better choice. Silastic and methyl methacrylate have been shown to incite host foreign body reactions that increase the risk of infection and extrusion (22). Autoimmune rejection is also possible and may necessitate implant removal.

Another substance historically used widely for dermal augmentation is injectable bovine collagen. Hypersensitivity manifests as skin inflammation or gastrointestinal distress after eating beef. Each prospective patient is carefully evaluated for a history of hypersensitivity to beef products before treatment and is observed closely after collagen injections. A positive reaction to a skin test dose is an absolute contraindication to collagen injection. If a reaction occurs, it is managed medically with topical and systemic antiinflammatory agents and local skin care. The injected tissue is removed surgically if the reaction cannot be controlled conservatively. These risks are one of the underlying reasons for removal from the current market in the United States. Acellular human dermis is available in thin sheets and can be used for soft tissue augmentation. It can be used safely in most previously irradiated fields (23,24).

Other threats to implant failure include bleeding, trauma to the implant, and implant malposition. Postoperative hematoma or seroma formation must be treated as soon as possible, or at the least closely monitored. If a vascular patch or area of revascularization begins bleeding, the patient is returned immediately to the operating room for repair of the leak. Few crises are worse than vascular emergencies in surgical implants in the face, head, and neck.

Micromotion of an implant is expected and desirable, because the implant must closely simulate the characteristics of the host tissue. However, macromotion is possible unless the implant is firmly secured to the underlying tissue. Migration or malposition of an implant may

TABLE 172.3 COMPLICATIONS

Complication	Prevention	Treatment
Infection	Perioperative antibiotics, aseptic technique	Antibiotics, hot compresses
Traumatic displacement	Patient education, implant stabilization	Surgical repositioning
Impending extrusion	Control of infection, immobilization of site	Removal of implant
Over- or undercorrection	Use of scans, photos, and measurements preoperatively	Revision according to patient's wishes
Malposition	Implant stabilization	Surgical repositioning
Bleeding	Meticulous hemostasis, compression	Surgical exploration
Patient dissatisfaction	Preoperative counseling, communication, and rapport	Reassurance and concern, revision if necessary

necessitate a second operation to realign or fixate the device. Undercorrection or overcorrection of a deformity is corrected only if the patient chooses to do so, without urging by the surgeon.

If a patient is dissatisfied with the results of a surgical implant, the surgeon reassures the patient until the swelling has subsided enough to gain an impression of the result. The patient–physician relationship is maintained with a demeanor of concern, trust, and free communication. If the patient's dissatisfaction is justified, the surgeon can discuss the possibility of surgical revision. If the patient's concern is not justified, a second opinion from a respected colleague can defuse the situation. Whatever the conditions, the physician maintains a close and empathic relationship with the patient. Table 172.3 summarizes the complications and emergencies in the use of implants as well as prevention and management.

Local Cutaneous Flaps and Grafts

173

Brian Jewett

Facial reconstruction is a challenging yet rewarding endeavor. Repair of facial defects requires an appreciation of variations in facial cutaneous tissue and the influence of these differences on use of potential reconstructive methods. Multiple factors help determine the optimal method of repair, including the size of the defect, the depth and location of the defect, and the strength of the underlying facial framework. Maintaining symmetry, contour, and function is essential for a successful facial reconstruction. Finally, of utmost importance is a thorough understanding of all appropriate reconstructive options.

SKIN ANATOMY

Skin variability in color, texture, thickness, and accessory components is demonstrated from one anatomic region to another, and an understanding of these variations is important for optimizing wound healing and soft tissue restoration. Skin consists of an epidermal component with appendages and a dermal component with neurovascular supply.

The epidermis consists of predominantly keratinocytes (80%) but also melanocytes, Langerhans cells, and Merkel cells (Table 173.1). The basal layer, spinous layer, granular layer, and cornified layer make up four distinct histologic layers, with the deepest layer, the basal layer, serving as the germinative layer. Melanocytes are dendritic, pigment-synthesizing cells of neural crest origin with clear cytoplasm, and they are confined to the basal layer. Melanin is produced by melanocytes, which is transported to adjacent basal and spinous layers for engulfment by the keratinocytes. Once engulfed, the melanin is arranged as a cover over the nuclei, serving as a protective barrier against ultraviolet irradiation. Langerhans cells are derived from bone marrow and serve to process and present antigens. These cells are found in the suprabasal epidermal layers, have dendritic processes, and contain Birbeck or Langerhans cell granules (1). Merkel cells are mechanoreceptors of neural crest origin and are primarily involved with touch sensation. Merkel cells are usually found in areas of high tactile sensitivity, where they aggregate to form tactile disks and Merkel cell–neurite complexes (2).

The dermal–epidermal junction is a critical structure that helps prevent dermal–epidermal separation, and alterations in the structure are found in diseases like epidermolysis bullosa (3). Keratin filaments within the basal keratinocyte condense and attach to an electron-dense plaque at the inferior portion of the cell membrane known as the hemidesmosome. Anchoring filaments in the lamina lucida connect hemidesmosomes to the lamina densa, which in turn is connected to the anchoring plaques in the dermis by anchoring fibrils.

Epidermal appendages include hair follicles, sebaceous glands, and eccrine and apocrine sweat glands. Pilosebaceous units contain hair follicles, sebaceous glands, arrector pili muscles, and sensory end organs. The pilosebaceous unit has motor and sensory functions, while also producing hair and sebum. On the nasal tip, the sebaceous component of the pilosebaceous unit is most prominent, while on hair-bearing surfaces, the follicular component predominates. Complete units are absent on the soils, palms, and mucous membranes. Healing of partial-thickness wounds by secondary intention is facilitated by pilosebaceous units, since reepithelialization occurs in part from the epithelial cells that line the follicular unit. Sebaceous glands connect to the hair follicle by a squamous epithelial duct, allowing the glands to secrete sebum through the duct, along the follicle, and onto the surface of the skin. Perhaps providing a protective function, sebum acts as an emollient to the hair and skin. Eccrine sweat glands contain a secretory gland in the deep reticular dermis and a coiled intraepithelial duct that opens to the skin surface. These glands are controlled by the cholinergic system, and the duct can modify the composition of sweat secretion. Apocrine sweat glands receive adrenergic

innervation and are generally found in the eyelids (Moll glands), external auditory canal (ceruminous glands), axillae, areolae, and perineum (1).

The majority of skin consists of the dermis, which contains neural and vascular networks, epidermal appendages, fibroblasts, macrophages, mast cells, and other cells (Table 173.2). The extracellular matrix consists of collagen, elastin, and amorphous substance known as the "ground substance." Skin pliability, tensile strength, and elasticity are properties attributed to the dermal component, and the dermis is divided into the papillary (superficial) and reticular (deeper) layers. Fibroblasts produce collagen, mostly type I collagen, which is responsible for the tensile strength and elasticity of skin. Type III collagen is much less common, and is found in the papillary dermis. Matrix metalloproteinases degrade collagen, allowing new collagen to replace old fibers; however, induction of collagenases by ultraviolet radiation can lead to disorganization that is clinically manifested as skin wrinkling and photoaging. Fibroblasts also produce elastin, which is degraded by elastases, allowing a continuous regenerative process. Elastin fibers are perpendicular to skin surface in the papillary dermis and parallel in the reticular dermis. Ground substance is generated by fibroblasts and consists primarily of proteoglycans, glycosaminoglycans, and filamentous glycoproteins. Ground substance is thought to help with distribution of pressure forces (1).

An abundant vascular supply is present in the skin, facilitating nutritional support and thermo regulation for the body. At the junction of the dermis and subcutaneous fat is the deep vascular plexus, whose arterioles supply the epidermal appendages and superficial vascular plexus. The superficial plexus lies in the reticular dermis and is connected to a vascular loop system in the papillary dermis, which provides nutrients to epidermal cells via diffusion.

TABLE 173.2 CONTENTS OF DERMIS

Blood vessels travel one of two ways to reach the cutaneous vascular plexus. Septocutaneous arteries travel through fascial septa, between muscular segments, parallel to the cutaneous surface. These arteries supply large areas of skin and have a pair of veins. Musculocutaneous arteries pass through muscle and are more common; however, these arteries typically supply smaller areas of cutaneous surface (Fig. 173.1) (4).

Sensory innervation includes both sensory and sympathetic nerves. Efferent nerves innervate blood vessels in the skin, and sensory nerves include dermal neural receptors known as Meissner (fine touch) and pacinian (deep pressure, vibration) corpuscles. Sensory nerves are distributed in a segmental fashion known as dermatomes.

SKIN BIOMECHANICAL PROPERTIES

The unique mechanical properties of skin influence cutaneous vascularity with tissue movement and ultimately flap survival. Skin is described as having a nonlinear stress–strain relationship, where stress represents force per unit of original cross-section and strain represents change in length divided by original length (5,6). With initial deformation, randomly oriented collagen and elastic fibers are stretched in the direction of the force, allowing extension with little force. With continued deformation, additional collagen fibers are recruited to load carrying capacity, but resistance transitions to eventual inability of further deformation with further force. At this point, no further collagen and elastic fibers can be oriented in the direction of the force and the structural integrity is protected against additional forces (7).

Skin is also characterized as being directional or anisotropic. The degree of skin tension is greatest parallel to the relaxed skin tension lines (RSTLs), a phenomenon that reflects interactions between collagen and elastic fibers at the cellular level. Lines of maximal extensibility (LME) run perpendicular to the RSTLs and represent lines of closure with the least tension (Fig. 173.2) (7–9).

Finally, skin is described as an elastic substance with lesser stress or force, but as a viscoelastic substance with higher stress loads. Higher stress loads cause skin to experience creep, which describes the increase in length with constant stress. Histologically, the increased length experienced is related to the displacement of interstitial fluid. Stress relaxation, although related to creep, defines the decrease in tension in skin overtime with constant tension (7). Larrabee showed that the effect of tension on flap survival is affected by flap length. Flaps with 3 cm base and 6 cm length showed necrosis, while flaps with the same base and 1.5 cm length all survived regardless of tension. Flaps with intermediate lengths were tension sensitive, with tension greater than 250 g tending to cause necrosis (10). Undermining is thought to reduce wound tension by releasing vertical attachments between the dermis and subcutaneous tissues, allowing less restricted movement.

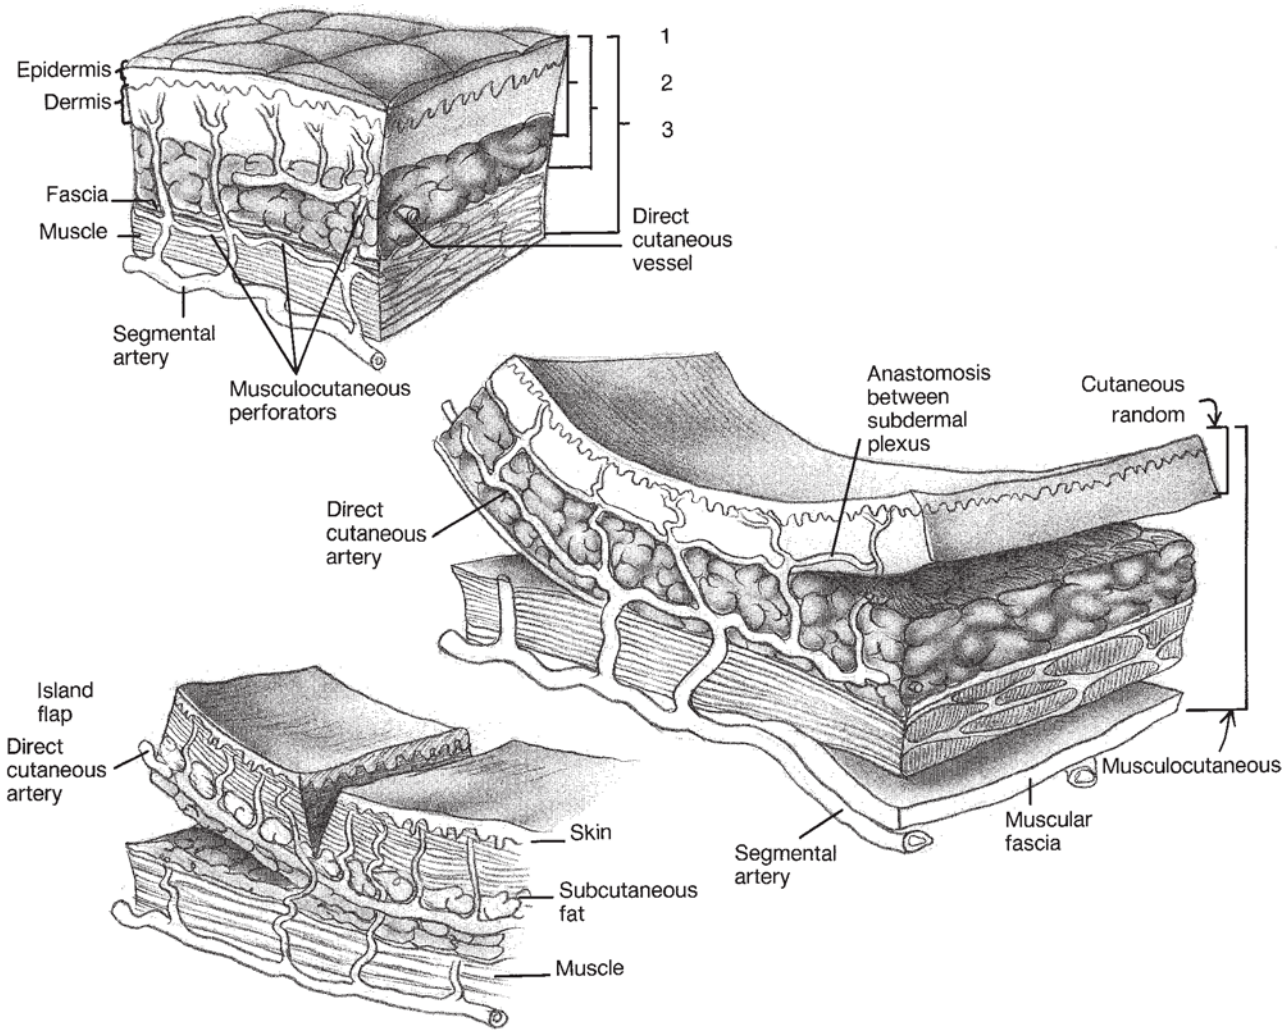

Figure 173.1 Representation of cutaneous vascular supply. Numbered parentheses delineate vascular supply for various types of flaps: *1*, random-pattern flaps; *2*, axial-pattern flaps; *3*, myocutaneous flaps.

SKIN PHYSIOLOGY

The vascular network within the skin facilitates regulation of body temperature and transfer of nutrients and other blood products, and the amount of blood flow is directly related to arteriolar pressure and flow (11). The precapillary sphincter controls the amount of nutritive blood flow to the skin (12), and this sphincter dilates with local hypoxemia (13). Preshunt sphincters, located deeper in the subcutaneous tissue, are regulated by the sympathetic nervous system, causing changes in blood flow that affects body temperature and systemic blood pressure (14). Vasodilatation can also occur with excessive body temperature, through local release of acetylcholine by sympathetic nerve fibers (4).

Revascularization is a complex process that is initiated after cutaneous injury or tissue transfer. Angiogenic stimuli lead to vasodilatation with increased vessel permeability. This is followed by dissolution of the basement membrane by proteases, allowing endothelial cells to migrate from the vascular wall toward the angiogenic stimulus. Nearby capillary sprouts anastomose with each other, forming loops. The blood vessels eventually differentiate to lay down basement membrane with type IV collagen, laminin, and proteoglycans. Some capillaries join preexisting vessels (inosculation), while others directly grow into the flap (neovascularization). Growth rate is about 0.2 mm/day, and regression of capillary loops occurs when the stimulus is discontinued after adequate vascular supply to the flap has been established (4). Revascularization adequate for detachment of a flap pedicle can be as early as 7 days (15), although waiting about 3 weeks is usually recommended.

Venous outflow is important, and venous occlusion can be more detrimental to tissue survival than adequate arterial supply. Venous outflow is generally through the subdermal plexus or with venous channels that accompany arteries within the flap. Cutaneous lymphatic drainage is also interrupted with tissue elevation, and increased

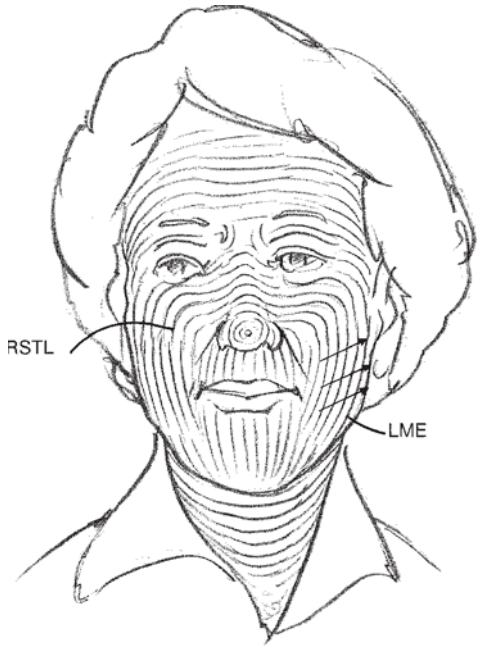

Figure 173.2 Relaxed skin tension lines (RSTLs) of the face. Notice that the lines of maximal extensibility (LME) run perpendicular to the RSTLs. Placing incisions along the RSTLs will decrease wound closure tension and optimize wound healing.

interstitial fluid pressure can affect capillary perfusion. Severing of sympathetic nerves leads to vasoconstriction (16) through the release of norepinephrine and oxygen-free radicals (17), but the depletion of neurotransmitters within 24 to 48 hours allows improvement in blood flow (18).

Delay of cutaneous flaps is thought to improve survival of the flap at the time of eventual transfer. Some theories used to explain the benefits of delay include improved blood supply after recovery from a hyperadrenergic state that is induced by sympathetic denervation (16,19) and permanent and irreversible dilation of the "choke" vessel through hyperplasia and hypertrophy (20). Both tobacco smoking and radiation have been shown to have a deleterious effect on flap survival, and delay of regional flaps is strongly considered in these patients (4).

DEFECT ANALYSIS AND PREPARATION

Analysis of a facial defect includes determining the depth of the wound, the color and texture of the missing skin, and the extent of involved aesthetic units and adjacent facial regions. In addition, the defect is inspected for any missing soft tissue, structural support, or lining. The thickness, texture, and mobility of remaining facial skin are assessed carefully; furthermore, any medical, social, and psychological issues pertaining to the patient should be considered. Finally, paramount to a successful reconstruction is appropriate assessment and treatment of any existing or potential functional compromise (i.e., nasal obstruction, eyelid malposition, oral incompetence) (Table 173.3).

TABLE 173.3 KEYPOINTS—FACIAL DEFECT ANALYSIS

Depth, size, and location of defect
Color, thickness, laxity of adjacent skin
Aesthetic units and landmarks
Nearby structures that cannot be distorted
Existing or potential functional compromise

Facial defects occasionally involve multiple areas of the face. When planning reconstructive options, it is helpful to demarcate the division between the primary and surrounding facial regions such that defects involving multiple facial regions are repaired with separate methods addressing each region. Adhering to this principle places eventual scars along boundary lines that separate each aesthetic region, which helps preserve the natural contours of the face.

Within each region, individual aesthetic units should be identified. Aesthetic units are based on variations in skin thickness and texture, as well as variations in contour created by the underlying facial framework (Fig. 173.3). Optimal repair of a facial defect may require repositioning of skin and soft tissue within an involved aesthetic unit, thereby allowing eventual scars to lie within zones of transitions between adjacent units. In addition, small defects may be enlarged to facilitate repair of an entire aesthetic unit by a single repair method.

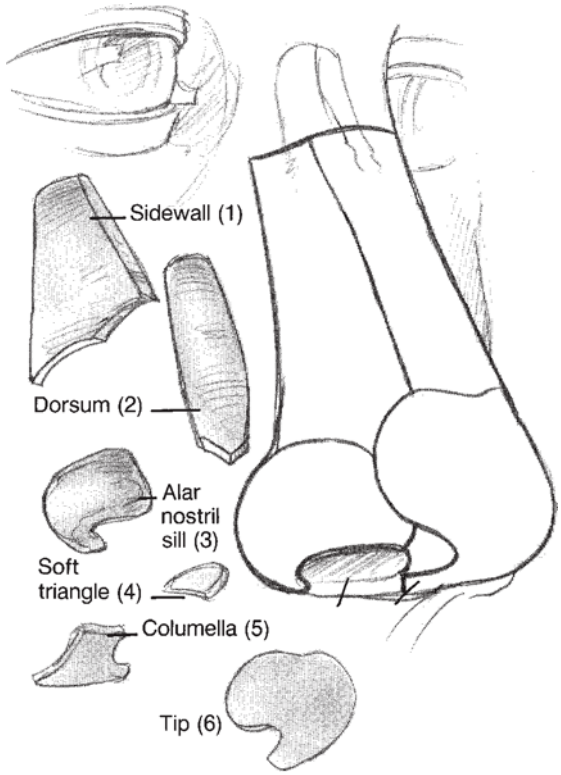

Figure 173.3 Nasal aesthetic subunits.

TABLE 173.4 LADDER OF FACIAL CUTANEOUS RECONSTRUCTIVE OPTIONS

Healing by secondary intention
Primary wound closure
Skin or composite grafts
Local cutaneous flaps
Regional cutaneous flaps
Distant tissue transfer

Establishing uniform depth, while maintaining symmetry with contralateral facial structures, is equally important. Beveled tissue at the periphery of the Mohs defect is removed if flaps are planned, in order to optimize eversion of skin edges at closure. In addition, cutaneous edges of the flap and the recipient tissue are adjusted appropriately to establish uniform thickness at the line of closure. Whenever possible, the primary defect should be deepened to establish uniformity rather than thinning the flap. One exception to removing beveled edges is when skin grafts are performed. In this circumstance, beveled edges are freshened, but maintained, to provide a gradual contour transition between recipient tissue and the skin graft. Additional techniques helpful in optimizing repair include angulation of curvilinear defects, since round defects are more likely to undergo concentric scar contraction and result in trapdoor deformity. Modifying the periphery of the defect by creating more acute angles often reduces the risk of this deformity.

Facial defects are repaired using a number of options, including healing by secondary intention, primary closure, local and regional flaps, skin grafts, composite grafts, and free tissue transfer (Table 173.4). Occasionally, cartilage grafts or subcutaneous augmentation flaps are also necessary to establish appropriate support as well as contour match with the tissue surrounding the defect. Selection of the optimal reconstructive method is influenced by the size, depth, and location of the facial defect (Table 173.5).

PATIENT PREPARATION—MEDICAL COMORBIDITIES

Systemic diseases such as diabetes, malnutrition, arteriosclerosis, hypertension, and collagen vascular disease can compromise flap vascularity and lead to necrosis and impaired wound healing. Consulting with the patient's personal physician is important to ascertain whether the patient's medical condition is optimized during the perioperative period.

Patients with a history of irradiation have subcutaneous scar tissue and decreased vascularity of the skin in the irradiated area. Cutaneous flaps from adjacent nonirradiated tissue are preferred, but even then, healing may be compromised leading to poor outcome. When interpolated flaps are transferred to an irradiated area, detachment of the flaps is best delayed until revascularization of the flap is certain. For suitable candidates, consideration is given to hyperbaric oxygen treatment to optimize tissue oxygenation levels prior to reconstruction.

Patients are questioned preoperatively concerning their use of tobacco and alcohol. Heavy alcohol consumption will dilate blood vessels, predisposing to hematoma formation. Avoidance of alcohol during the perioperative period is recommended. Ideally, tobacco and nicotine products should be avoided, at least 8 weeks before and after surgery. Even smoking cessation for 2 days before surgery and 7 days after surgery has been shown to have beneficial effects on flap survival. Smokers develop skin necrosis three times more frequently than nonsmokers, and the extent and depth of skin slough are more severe (21). Nicotine causes systemic vasoconstriction through activation of the adrenergic nervous system, which may lower tissue oxygenation pressure by greater than

TABLE 173.5 COMPARISON OF RECONSTRUCTIVE OPTIONS

Option	Advantages	Disadvantages
Healing by secondary intention	No further surgery required	Extended wound care. May result in depressed, hypopigmented scar. Contracture may distort adjacent structures.
Primary closure	Technically quick and straightforward Usually good aesthetic outcome	May require excision of additional normal skin if rounded defect Use usually limited to defects that lie along RSTLs
Cutaneous graft	Technically quick and straightforward	Donor site required Potentially poor match in cutaneous color, texture, and contour Longer wound care. Not always complete survival.
Local cutaneous flap	Easy wound care Short healing period Usually complete survival Excellent color and contour match	May be technically challenging Creates additional scars Secondary defect may cause distortion. Increased risk of bruising, swelling, trapdoor deformity Potential for greater reconstructive challenge with failure

50%. This occurs within 10 minutes of smoking a cigarette and lasts approximately 50 minutes. Smoking also produces carbon monoxide, which has a higher affinity for hemoglobin than oxygen, thereby producing high levels of carboxyhemoglobin (22–26). When possible, consideration is given to delaying surgical procedures until smoking cessation can be assured.

HEALING BY SECONDARY INTENTION

Small superficial cutaneous defects involving concave facial surfaces may granulate and epithelialize with an acceptable aesthetic result. Ideal locations for healing by secondary intention include the temple and medial canthus. It is imperative to keep wounds moist during the healing phase. Wounds are cleaned twice daily, removing fibrinous debris during each cleaning. Wounds are then covered with a topical water-based ointment containing mupirocin and nonadherent gauze for the initial 2 weeks, followed by a topical petroleum-based ointment and nonadherent gauze until complete reepithelialization occurs. For patients with larger defects or concerns for slower wound healing, wet-to-dry dressings are employed daily. These patients are instructed to place a moist, but not dripping wet, gauze to the wound in the evening, followed by removal in the morning. The morning wound care is as previously described, with topical ointment application and nonadherent gauze. Patients are counseled that wounds often take 4 to 6 weeks to heal, and massage may be indicated to address any contour irregularities. Patients may be offered resurfacing procedures if surface irregularities are persistent.

PRIMARY CLOSURE

Adjacent facial tissue provides the ideal color, thickness, and texture for repair of most facial defects. Unfortunately, scars associated with primary closure or local flaps do not always fall along borders between aesthetic units; nonetheless, the benefits gained in establishing appropriate contour and skin color may outweigh this potential disadvantage. In general, oval and linear defects along RSTLs in a patient with redundant skin are ideal defects for primary closure; in addition, an M-plasty modification can be performed to shorten the length of the anticipated scar (Fig. 173.4). Modification of underlying facial tissue or framework may facilitate wound closure (i.e., dorsal nasal framework modification), and suspension sutures may be indicated to prevent distortion of mobile structures (i.e., canthal, nasal valve, and alar suspension sutures).

Wide undermining of the skin adjacent to the defect is performed in subcutaneous plane for most facial defects; however, with nasal defects, the dissection is usually performed in a submuscular plane. Dissection in an appropriate plane minimizes bleeding and postoperative bruising,

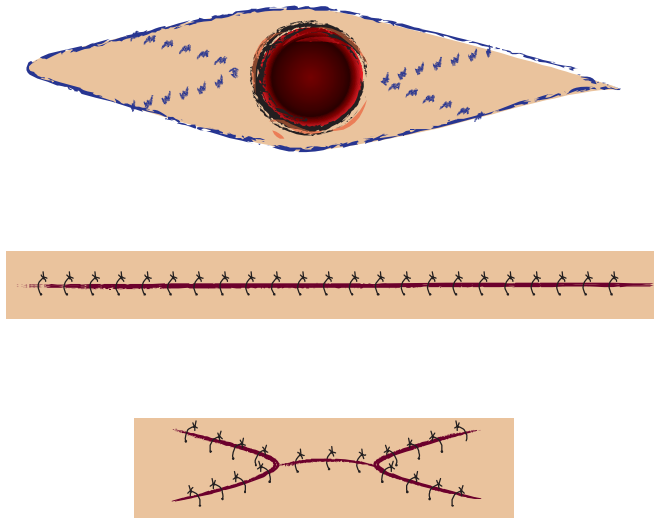

Figure 173.4 Comparison of the closure of a fusiform excision and an M-plasty excision. The straight portion of the M-plasty closure is significantly shorter than the fusiform closure.

and wide undermining helps avoid trapdoor deformity. The effect of primary closure on surrounding structures such as the nasal tip, alar margin, eyelid, canthus, oral commissure, and hairline should be evaluated. The method of repair should be reconsidered if there is significant distortion that is not expected to resolve with time and postoperative massage.

FACIAL CUTANEOUS FLAPS

When primary wound closure is not possible, local flaps from adjacent facial cutaneous tissue may be used to repair defects. Repair with local flaps may be limited by the laxity of the donor skin, and thorough analysis of blood supply, wound closure tension (Table 173.6), and strength of the underlying facial framework should be performed prior to performing a cutaneous flap. Cartilage grafting or suspension sutures may be necessary to prevent distortion of

TABLE 173.6 FACIAL CUTANEOUS FLAPS KEY DEFINITIONS

Secondary defect	Wound created when skin flap is transferred to the primary defect—goal is to place secondary defect in area of greatest tissue laxity.
Primary tissue movement	Movement of flap to defect
Secondary tissue movement	Displacement of skin surrounding defect toward center of wound usually secondary to wound closure tension and movement of tissue to close the donor site

Flap design and method of tissue movement

mobile or weaker structures. Standing cutaneous deformities should be anticipated, and incisions should be placed along aesthetic borders or RSTLs when possible. Occasionally, flaps are combined with skin grafting for cutaneous restoration.

Flap Classification and Description

Cutaneous flaps are generally described as having skin and subcutaneous tissue with direct vascular supply and are usually transferred to an immediately adjacent or nearby location. Flaps can be classified based on (a) location, (b) vascular supply, and/or (c) flap design and method of tissue movement (Table 173.7).

Flaps may be classified based on location of flap relative to the defect. Local cutaneous flaps involve use of tissue immediately adjacent to or near the defect. Regional flap involves use of tissue from outside of the face, scalp, or neck, where arterial pedicle is sufficient to reach the facial defect (pectoralis muscle flap). Distant flaps involve harvesting of tissue from a distant location, requiring microvascular anastomosis of vessels (free flap tissue transfer).

Flaps may also be classified based on vascular supply, being described as having random or axial vascular supply (Tables 173.8 and 173.9). Random cutaneous flaps are supplied by musculocutaneous arteries near the flap base, and blood travels to the tip of the flap via the interconnecting subdermal plexus. Survival of random cutaneous flaps depends on the physical properties of the supplying vessels and the perfusion pressure (27). Flap necrosis occurs when perfusion pressure drops below the critical closing pressure of the arterioles in the subdermal plexus and there is not improved survival with a wider flap base if the arteriolar pressure remains the same (28). Axial cutaneous flaps have a greater likelihood of survival compared to random cutaneous flaps, with the survival advantage largely related to the incorporation of a septocutaneous artery within the longitudinal axis. Survival is related to the length of the

included artery, and vascular supply to the portion of skin beyond the direct arterial supply is based on the subdermal plexus, similar to a random cutaneous flap.

Flaps may be described based on the method of tissue movement and include three general types: pivotal, advancement, and hinge flaps (Table 173.10). Each of these methods will be described in more detail with the following discussion.

Pivotal Flaps

Pivotal flaps move toward the center of the wound by pivoting around a fixed point at the base of the flap pedicle, and examples include rotation, transposition, and interpolation. In general, the greater the pivot of the flap, the shorter the effective length of the flap. The effective length is reduced 5%, 15%, and 40% for flaps pivoted 45, 90, and 180 degrees, respectively (29). When designing a pivotal flap, greater degrees of pivot usually require a longer flap to account for loss of effective length, and pivoting greater than 90 degrees should be avoided. Incidentally, the greater the amount of pivot of the flap, the larger the amount of redundant tissue at the base (standing cutaneous deformity).

Rotation Flaps

Rotation flaps are pivotal flaps with curvilinear design (Fig. 173.5). In general, rotation flaps involve transfer of tissue immediately adjacent to the defect and are best used for repair of triangular defects. When rotation flaps involve pivoting of tissue only, and no advancement component, the greatest wound closure tension has been shown to be at the site perpendicular to the periphery of the flap (30).

TABLE 173.10 FLAP CLASSIFICATION BY DESIGN AND METHOD OF MOVEMENT

Hinge flaps

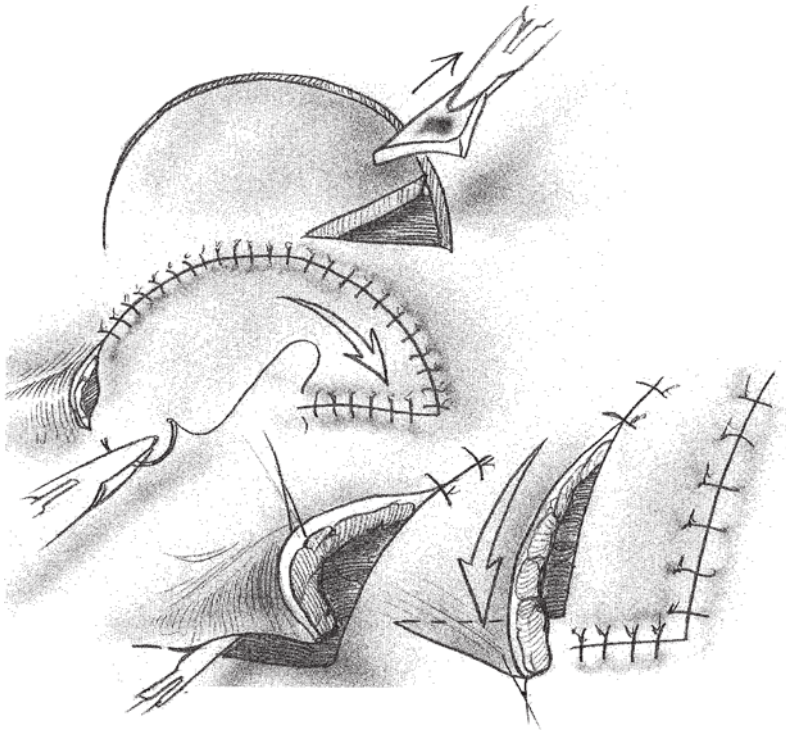

Figure 173.5 Rotation flap with semicircular design. Standing cutaneous deformity is removed at the base of the donor site.

Classically, rotation flaps are designed so that the length of the arc incision is four times the width of the defect. This configuration minimizes the need for any modifications. Rotation flaps have great flexibility in design, and position should be optimized so the flap border falls along aesthetic borders or RSTLs; in addition, flaps should be inferiorly based to facilitate lymphatic drainage. If the defect is not triangular, the defect can be modified to allow for removal of the standing cutaneous deformity at the inferior edge of the defect, thereby converting the wound to a triangular shape. Bilateral rotation flaps can be designed, with opposing flaps both transferred along curvilinear borders into the defect. When two opposing flaps are used, they result in a T-shaped scar (known as an O-to-T closure). Opposing rotation flaps can be of unequal lengths, depending on the surrounding tissue, aesthetic borders, and anatomic structures. A facial location that is particularly amenable to closure using opposing rotation flaps is the temple, with the T-shaped incision placed along the lateral canthal creases and the hairline.

When necessary, rotation flaps can be modified to reposition the standing cutaneous deformity, optimize wound closure tension, and facilitate skin redrapage. Modifications include a back cut at the base of the flap, which changes the position of the pivot point to lessen wound closure tension. In addition, this technique allows removal of the standing cutaneous deformity at the back cut, which may fall in a more optimal location such as a facial aesthetic border. Care must be taken when removing tissue at the flap base, since this may compromise the vascularity of the flap. Redundant tissue can also be removed anywhere along the curvilinear arc, equalizing the length discrepancy between the flap's border with the adjacent defect border. Typically, the redundant tissue is removed in a triangular fashion, with excision width similar to defect width, and effort is made to place excision in an optimal position for scarring. Other modifications include changing the method of transfer from purely pivotal to include some degree of advancement as well.

Transposition Flaps

Transposition flaps transfer adjacent tissue about a pivot point but have a linear configuration (Fig. 173.6). Similar to rotation flaps, the greater the degree of pivot, the lesser the effective length of the flap and the greater the size of the standing cutaneous deformity. Wound closure tension is greatest at the closure site of the secondary defect adjacent to the base of the flap. Transposition flaps created from thick skin have limited mobility and produce larger standing cutaneous deformities and excessive wound closure tension. Design of transposition flaps with angulated borders reduces the likelihood of trapdoor deformity, which is commonly seen with curvilinear scars (31). Transposition flaps are generally pivotal but may also involve some degree of advancement. Two types of frequently used transposition flaps are rhombic flaps and bilobed flaps.

Rhombic flaps involve repair of a defect that resembles a parallelogram, having all sides equal with angles at 60 and 120 degrees opposing each other. The flap design involves extending the short diagonal of the parallelogram a distance equal to one side. Subsequently, a second incision is made parallel to one of the adjacent borders, again

the same length. With this technique, with every rhombus defect, four potential flaps can be designed (Fig. 173.7). Selection of flap location relative to the defect should be considered carefully and selected based on avoidance of distortion of surrounding anatomical structures and minimizing wound closure tension by recruitment of tissue laxity. One disadvantage of the rhombic flap is the difficulty in having the majority of the scar fall within RSTLs, and for this reason, some surgeons utilize this flap less frequently in reconstruction of facial defects.

The bilobed flap is a double transposition flap with a single base (Figs. 173.8 and 173.9). The classic design involved pivoting each lobe 90 degrees, resulting in a total transposition of 180 degrees. The design was modified by Zitelli, having each lobe be 45 to 50 degrees, with total transposition under 100 degrees. This modification decreased the wound closure tension and lessened the standing cutaneous deformity (32). Similar to rhombic flaps, a disadvantage is the difficulty in having scars fall within RSTLs; however, the flap is commonly used for nasal

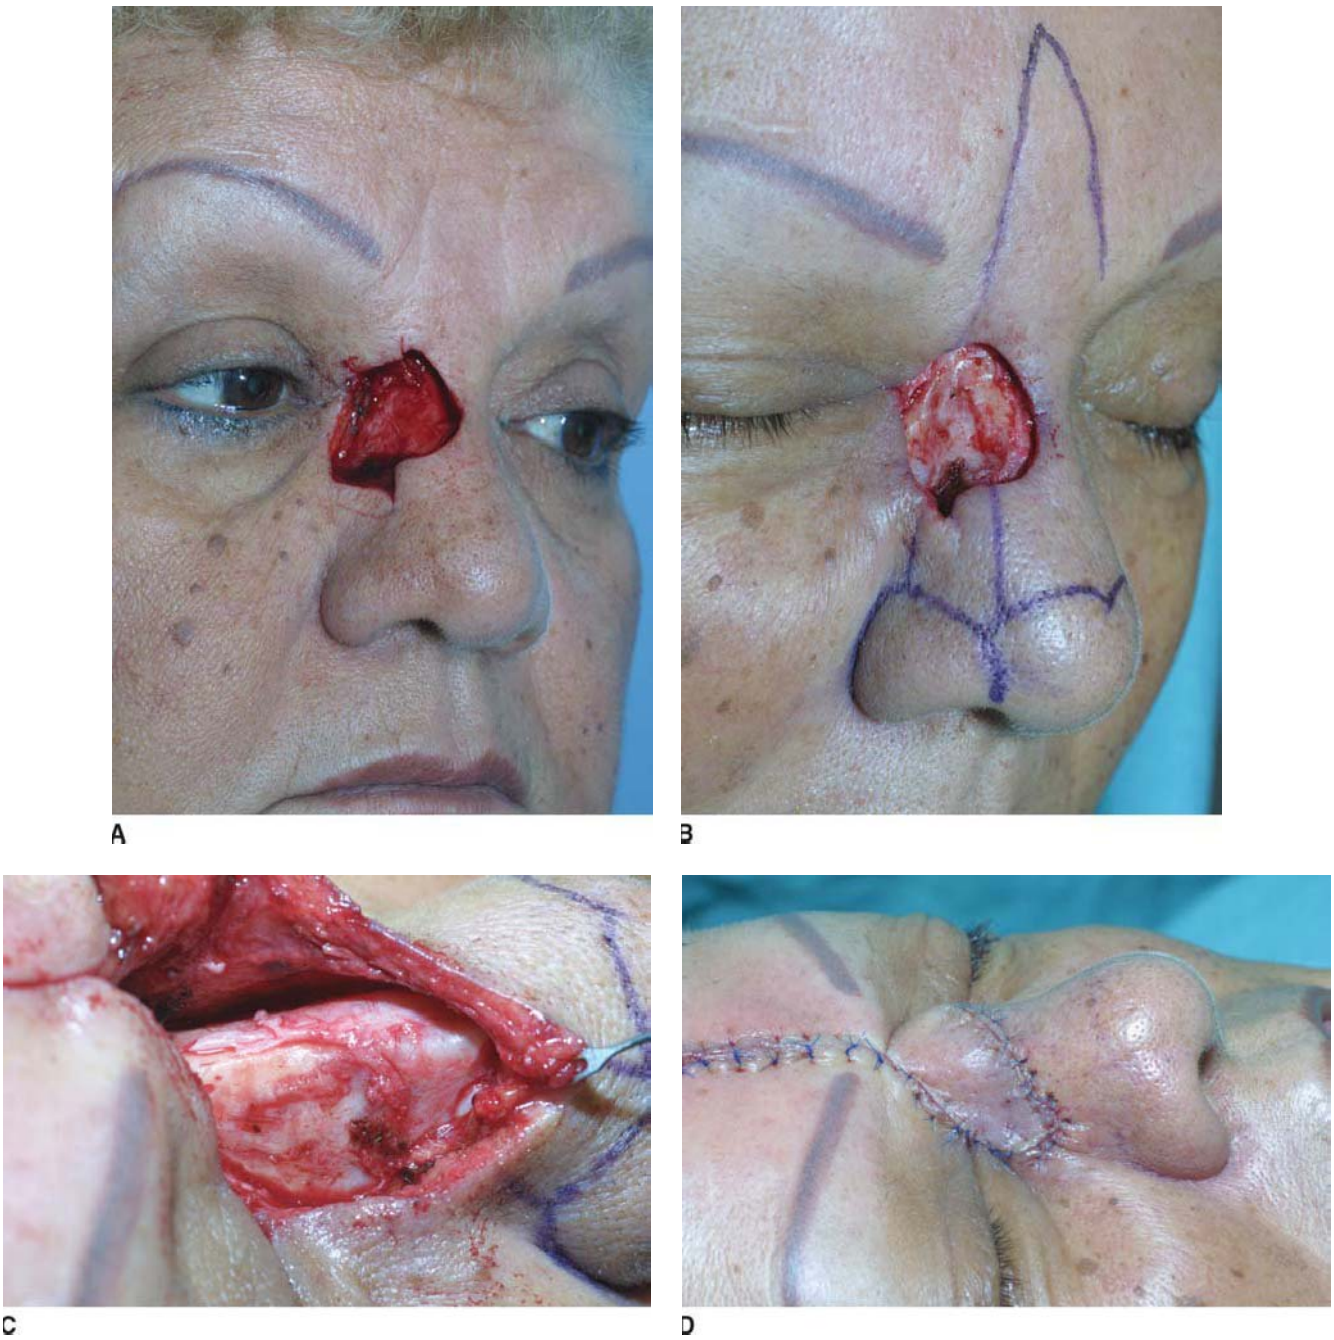

Figure 173.6 Glabellar flap. **A:** A patient with nasal defect following Mohs excision of skin cancer; **(B)** glabellar flap designed; **(C)** wide undermining of flap across nasal framework; **(D)** wound closure;

reconstruction, especially tip and supratip defects, since the double lobe design allows for recruitment of tissue from areas of greater tissue laxity such as the nasal sidewall.

The primary lobe of the bilobed flap, usually the same size as the defect, is used to restore the defect and the secondary lobe, generally 80% to 85% the size of the defect, is used to repair the donor site of the primary lobe. The donor site of the secondary lobe is closed primarily. Variations in the size of each lobe are based on differences in cutaneous thickness. If the lobe is located within an

area of thick, noncompliant, immobile facial tissue, it is imperative to make the lobe the same size as the defect since limited mobility and stretch is expected. Undersizing of the primary or secondary lobe will result in increased wound tension, poor scarring, and distortion of surrounding facial structures. In addition, oversizing of the flap predisposes to trapdoor deformity and uneven contours. Hence, judicious sizing is necessary and is dependent on the texture and thickness of the skin and tissue being transposed. In general, ideal patients have thin, mobile skin, while patients

with thick, sebaceous skin have less mobility for transfer and increased risk of developing necrosis, trapdoor deformity, and depressed scars. An anticipated standing cutaneous deformity is removed, whenever possible, within an incisional line hidden along an aesthetic unit boundary.

Bilobed flaps on the nose are ideally based laterally and are best used to repair defects located on the central or lateral nasal tip that are less than 1.5 cm in diameter. When possible, the axis of the secondary lobe is placed perpendicular to the alar rim. In so doing, displacement of the alar rim by closure of the secondary lobe donor site is minimized. An ideal defect location for this technique is the zone of transition between the tip, ala, and sidewall. Use of the bilobed flap for alar reconstruction is avoided because crossing the alar groove with the pedicle causes distortion of this nasal landmark (33).

Interpolation Flaps

Interpolation flaps are similar to transposition flaps in that they have pivotal movement; however, the base of interpolated flaps is not contiguous with the defect resulting in a pedicle that spans over intervening cutaneous tissue. Interpolation flaps require secondary detachment, once recipient vascular supply to the flap has been established. Common examples of interpolation flaps include the paramedian forehead flap (Fig. 173.10) and the melolabial flap used in nasal reconstruction. Both are detailed in a separate section in this textbook and will not be further discussed in this chapter. Other examples include the lip crossover flap and the postauricular flap, both used for the repair of full-thickness defects involving the lip and ear, respectively.

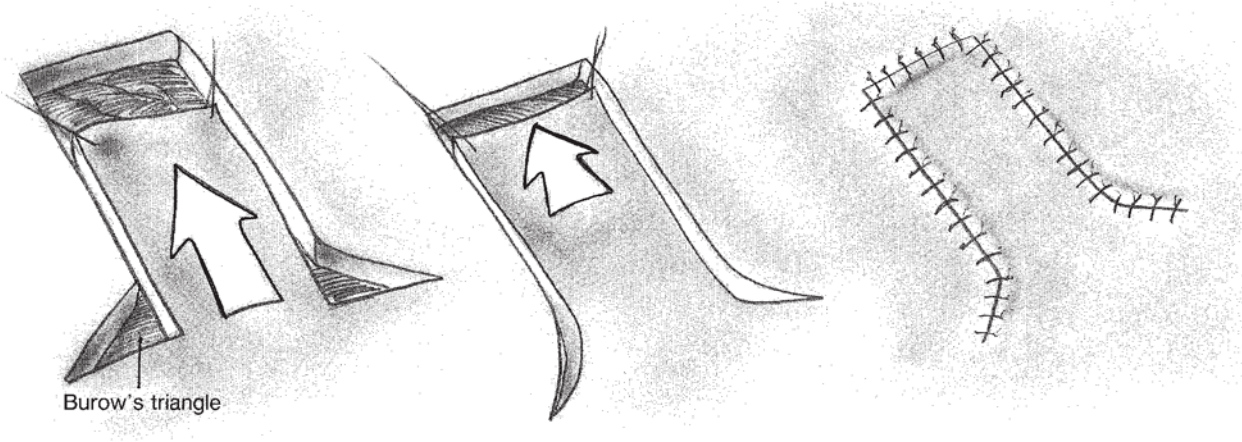

Figure 173.11 Monopedicled advancement flap. Flap is incised and transferred across the defect. Standing cutaneous deformities are excised at the base of the donor tissue.

Advancement Flaps

Advancement flaps have a linear design and are moved directly to the defect. These flaps are mobilized by undermining of tissue and inevitably have some component of "stretching" of tissue; hence, advancement flaps are most successful in areas of greatest tissue laxity and extensibility. Examples of advancement flaps include unipedicle, bipedicle, V-Y, Y-V, and island advancement flaps. Primary closure is the simplest form of advancement, requiring only undermining and advancement of tissue without releasing incisions to facilitate tissue movement. Primary closure generates standing cutaneous deformities that are ideally removed along RSTLs.

Uni- and Bipedicled Advancement Flaps

Unipedicled flaps involve parallel incisions with movement of tissue spanning over defect. Repair is completed with primary and secondary tissue movement. Given the length discrepancy between flap borders and recipient tissue, standing cutaneous deformities develop along both incisions and can be incised at any favorable point along the incision lines. Effort is made to place incisions along RSTLs, and bilateral flaps can be employed (Fig. 173.11). When two flaps are used, they are opposing and result in an H-shaped scar (Fig. 173.12). Opposing advancement flaps can be of unequal lengths, depending on the surrounding tissue laxity, aesthetic borders, and anatomic structures. Unipedicled flaps may be employed in the repair of forehead defects, where the longest portions of the H-shaped incisions are placed within the horizontal forehead creases. Bipedicled flaps involve transfer of tissue at a right angle to the defect, leaving a secondary defect that is commonly repaired with grafting. Bipedicled flaps may be used for scalp reconstruction, but more commonly, these flaps are used for vestibular lining repair of nasal alar defects.

V-Y and Y-V Advancement Flaps

V-Y advancement flaps involve "pushing" of central tissue, with closure of donor site by advancement of opposing wound borders. Wound closure tension is perpendicular to movement of central tissue, and this technique is commonly used for release and lengthening of contracted tissue. V-Y advancement can be used to correct distorted vermillion or eyelid borders. Y-V advancement involves creation of a triangular defect, followed by "pulling" of central tissue toward the defect. Wound closure tension is parallel to the central vector of the flap and is greatest at the apex of the flap. This technique is not commonly used in facial reconstruction but may be helpful in

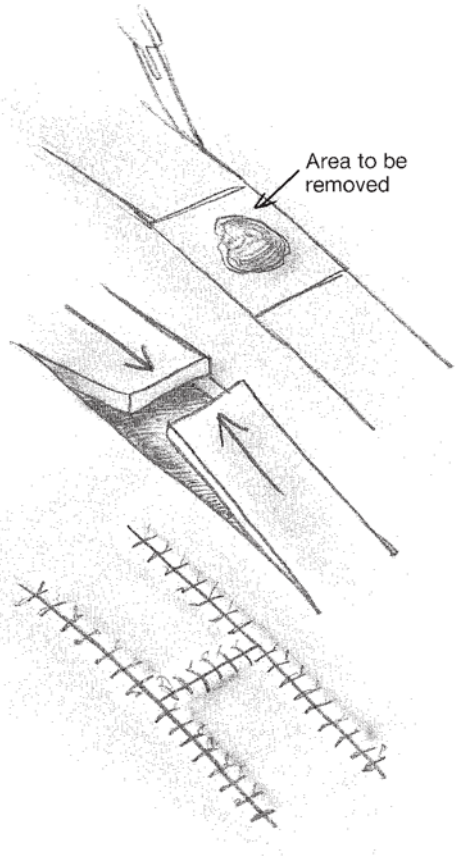

Figure 173.12 Bipedicled advancement flaps. Flaps are incised and transferred across the defect. Standing cutaneous deformities are excised at the base of the donor tissue.

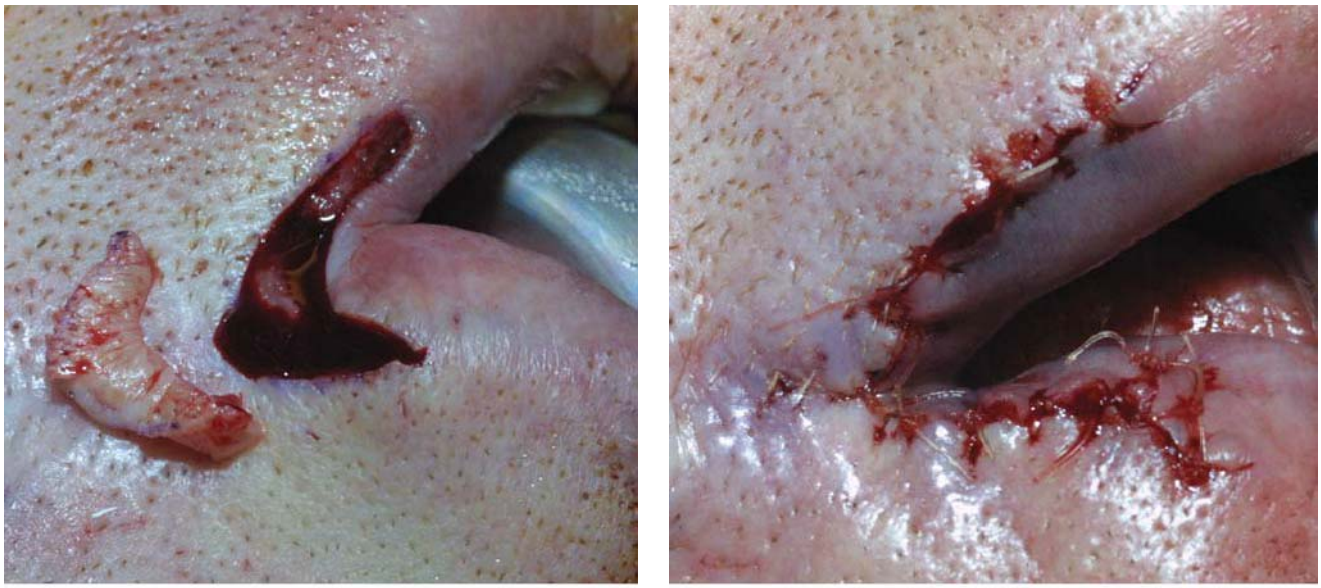

Figure 173.13 **A,B:** Commissuroplasty with Y to V flap.

restoring a distorted oral commissure (commissuroplasty) (Fig. 173.13).

Island Advancement Flaps

Island advancement flaps involve transfer of an "island" of cutaneous tissue, incised on all borders, with a pedicle of subcutaneous tissue containing sufficient vascular supply. Dissection is performed for the medial and lateral thirds of the flap, maintaining a central island pedicle with random arterial supply. Island advancement flaps can be rotated and/or advanced to the defect, but for facial defects, the flaps are more commonly advanced. An example of rotation would include rotation along the melolabial crease for the repair of lip or medial cheek defects (Fig. 173.14). Design of the flap is largely dependent on the shape of the defect, surrounding anatomical structures, aesthetic

borders, and RSTLs. Patients with moderate skin thickness and sufficient tissue laxity are the best candidates, and flaps may need to be oversized to avoid distortion of anatomical structures adjacent to the defect. Wide undermining of adjacent tissue decreases the likelihood of trapdoor deformity and adjacent structure deformation. Island advancement flaps may be transferred over intervening cutaneous tissue and, thus, also be considered an interpolated flap in these circumstances.

Hinge Flaps

Cutaneous hinge flaps involve transfer of tissue by "flipping over" the tissue into the desired position and location, similar to turning the page in a book. This type of

flap may be of varied shape and is most commonly used for internal lining purposes. After transfer of the cutaneous hinge flap, the subcutaneous tissue that remains exposed is covered by a second cutaneous flap or graft. Vascularity is dependent on the tissue bordering the defect; hence, allowing the wound border to become well healed improves the vascularity of the cutaneous hinge flap. Subcutaneous hinge flaps involve transfer of only subcutaneous tissue in the same fashion and are most commonly for contour augmentation and/or coverage of cartilage grafts prior to cutaneous restoration.

Technique—Facial Cutaneous Flaps

In preparation for local flaps, the involved facial regions are injected with local anesthetic containing epinephrine in an appropriate plane to facilitate dissection and optimize hemostasis. The margins of the defect are freshened with a scalpel, removing the beveled edge from the Mohs resection. The flap is demarcated based on the size of the defect, and the flap and surrounding cutaneous tissue are elevated in an avascular plane, taking care to maintain a rich vascular supply to the flap. Wide undermining reduces trapdoor deformity and facilitates wound closure by reducing wound tension (Table 173.11).

The donor site is closed first, followed by suturing the flap in place. Polydioxanone or poliglecaprone sutures are used for subcutaneous closure, and polypropylene vertical mattress and running sutures are used for cutaneous closure. Bacitracin is applied and a compression dressing consisting of a nonadherent dressing, cotton balls, and expandable tape is placed for 24 hours. Cutaneous sutures are removed in 5 to 7 days.

Facial cutaneous flaps have the potential to distort normal facial anatomy, leading to anatomic asymmetries, retraction or distortion, and functional compromise. Careful planning and selective use of flaps minimize these potential complications; furthermore, judicious use of cartilage grafting is recommended. Cartilage grafts can be harvested from septum or the conchal bowl, and grafts are sewn in place using polyglactin mattress sutures. Cartilage grafts are commonly used along the alar rim to prevent notching. Suspension sutures may be used in the area of nasal sesamoid cartilages, spanning toward the pyriform aperture, to address any potential nasal valve collapse. Suspension sutures may also be used at the lateral and medial canthus in the form of a canthopexy or canthoplasty, in order to address any potential eyelid malposition.

FACIAL CUTANEOUS GRAFTS

Occasionally, superficial and/or extensive facial defects are best addressed by repair with a skin or composite graft (Table 173.12). Placement of a graft obviates the need for additional scars on the face as is seen with other reconstructive methods; however, most grafts have a "patched" appearance with discrepancies in color and texture between native and grafted facial skin. Postoperative resurfacing procedures may minimize these color and texture discrepancies.

Skin graft viability depends on several factors: blood supply to the recipient site, microcirculation on the surface of the recipient site, vascularity of donor graft tissue, contact between the graft and recipient site, and certain systemic illnesses. Contact between the skin graft and recipient site is essential, and a bolster dressing prevents fluid collections and shearing forces from disrupting fibrous connections between the graft and wound bed. Systemic illnesses that may compromise graft survival include inflammatory conditions, hematologic disorders, diabetes, nutritional deficiencies, and hypoxemia (34). Use of tobacco products is also detrimental to the survival of skin grafts.

Recipient site conditions that are not favorable to graft survival include irradiated tissue, excessive fibrosis, exposed bone, cartilage, or tendon. Grafts placed over avascular defects smaller than 1 cm^2 may survive through nutritional support via wound edges; however, grafting over avascular wounds larger than this is unlikely to succeed (34).

Split-Thickness Grafts

Split-thickness grafts consist of epidermis and a variable portion of underlying dermis, and most surgeons harvest these grafts with a dermatome so as to contain epidermis and minimal to no dermal tissue. Because of their poor color and texture match with normal skin and their tendency to contract, split-thickness skin grafts are rarely used to replace cutaneous tissue in facial reconstruction.

Full-Thickness Grafts

Full-thickness skin grafts consist of epidermis and full-thickness dermis. They resist contraction, have texture and pigmentation similar to normal skin, and require a well-vascularized, uncontaminated wound site for survival. Full-thickness grafts survive initially by diffusion of nutrition from fluid in the recipient site, a process known as plasma imbibition. This is followed by vascular inosculation, which usually occurs during the first 24 to 48 hours. After 48 to 72 hours, capillaries in the recipient site begin to grow into the graft to provide new circulation. By 3 to 5 days, a new blood supply has been established. Initially, full-thickness skin grafts appear blanched; however, over 3 to 7 days, a pink color develops signaling neovascularization. After 4 to 6 weeks, the pink color begins to fade, but the graft will often remain lighter than the surrounding skin, especially in darker skinned individuals.

Compared to split thickness, full-thickness grafts have the advantage of better color and texture match, less contour irregularities, no need for special equipment, and easier donor site wound care. The disadvantages may include reduced survival rate for larger grafts and longer healing time (34). The ideal facial defect to repair with a full-thickness skin graft is superficial, with loss of skin, but not underlying muscle or soft tissue. The vascularity of shallow wounds is greater than that for defects extending underlying cartilage or bone. There is a wide variation of facial skin thickness among individuals, and the overall thickness of the facial skin is an important preoperative consideration. For similar facial defects, a skin graft may provide a perfect match in terms of thickness for one person and a poor match for another.

A number of donor sites for skin grafts are available in most individuals, including the upper eyelid, forehead, melolabial fold, preauricular, postauricular, and supraclavicular areas. When selecting the donor site, the thickness and color of the recipient site skin are assessed, and the most optimal match in donor skin is determined. Skin from the postauricular area is preferred in men with skin defects of limited size because it is hairless and tends to have a similar thickness to the facial skin. Because men tend to have shorter hair than women, the postauricular skin is likely to have solar aging, which provides an improved skin color match with the facial skin. In contrast, preauricular skin is a better source for grafts in females. Preauricular skin in females is hairless and has more solar aging compared to postauricular skin, which is often covered by hair. The supraclavicular region is an excellent source for skin grafts, especially when a large graft is required. However, the supraclavicular skin is usually less sun exposed, creating a color discrepancy between the recipient skin and the skin graft. In addition, the supraclavicular skin can be much thicker than most facial skin, and judicious thinning of the graft is usually required.

There are occasions when skin grafts are used to repair defects even when it is anticipated that the graft will result in a contour depression or noticeable color discrepancy. These situations arise when caring for debilitated patients who have life-threatening illnesses. In addition, in patients who have malignancies showing aggressive growth patterns and tumor persistence or recurrence is a primary concern, skin grafts may be used as a temporary covering for a several years to facilitate tumor surveillance.

Locations particularly amenable to skin grafting include the temple, medial canthus, philtrum, and portions of the nose. The ideal nasal defects perhaps most amenable to a skin graft are separated from the free margin of the nostril by 5 mL and located in thin-skinned areas of the nose, such as the cephalic sidewalls, cephalic dorsum, and infratip lobule. Shallow wounds in these areas are typically completely filled by a full-thickness skin graft, thereby establishing confluent contour with the surrounding skin. The areas of the nose covered with thicker skin tend to heal with a contour depression and noticeable textural discrepancies between graft and adjacent facial skin. This is because the facial skin in these areas tends to have a more sebaceous nature than the graft.

If a full-thickness graft has been performed and a contour depression exists, the appearance can be improved by subsequent placement of a dermal fat graft after the skin graft has healed. Meyers et al. describe the use of dermal grafts at the time of skin graft placement to help prevent contour depression following repair of deeper defects. Their technique involves the placement of dermal tissue in linear strips within the wound bed, leaving adequate exposure of the underlying wound bed to provide nourishment to an overlying skin graft (35).

Defects located on the lateral nasal ala immediately adjacent to the nasal facial sulcus can be repaired with a number of options. If the defect extends into the cheek, the cheek component of the defect is usually repaired with a cheek advancement flap. The alar component can be repaired with a cheek or paramedian forehead flap if the defect is large. For smaller defects, especially in very young patients where preservation of regional flaps is desired, full-thickness skin grafts and composite grafts are considered for the alar portion of the defect. Full-thickness grafts are best suited for superficial defects not extending to the nostril border. In the case of deep alar defects, skin grafts do not lend any structural support, and subsequent nasal valve collapse may lead to compromise of the nasal airway. One option for patients with deep alar defects is the transfer of subcutaneous cheek tissue in the form of a hinge flap. The flap partially fills the defect and facilitates placement of an alar batten graft deep to the hinge flap. A full-thickness graft can then be placed as external covering over the hinge flap, thereby completing a single-stage reconstruction.

When defects of the nasal sidewall extend to the medial cheek, the cheek component of the defect is reconstructed

with a cutaneous advancement flap. The flap is advanced and anchored in place at the nasal facial sulcus with deep sutures that pass from the medial border of the flap to the periosteum of the nasal sidewall. A full-thickness skin graft is then used to resurface the sidewall. The cheek advancement flap facilitates positioning scars along the junctional zone between the aesthetic regions of the cheek and nose.

Staged Grafts

For deeper wounds, skin grafting may be delayed until granulation tissue has filled the wound bed (2 to 3 weeks), thereby reducing the likelihood of a step-down deformity at the edges of the graft. In addition, delay provides an improved vascular recipient site for the graft (36), which is especially important in areas of exposed periosteum or perichondrium. Development of sufficient granulation tissue may be improved by initial placement of an acellular dermal graft wound matrix to facilitate healing of wound bed prior to skin grafting. The acellular dermal graft wound matrix may be placed at the time of tissue resection, and wound care is dependent on the type of acellular dermal graft employed.

Following development of sufficient granulation tissue, any epithelium is removed prior to grafting and the tissue is cross-hatched so that myofibrils are released. Granulating wounds normally contain bacteria, and bacterial counts greater than 10^5 organisms per gram of tissue often lead to graft loss (37). When delayed grafting is planned, the patient is started on a course of an antistaphylococcal antibiotic several days prior to the delayed grafting procedure.

Technique—Facial Cutaneous Grafts

All patients undergoing skin grafting receive preoperative intravenous antibiotics, followed by 1 week of oral antibiotics. The bevel of the defect after Mohs excision is freshened, taking care to maintain a bevel to the skin edge, thereby smoothing the transition between the graft and recipient skin and lessening any contour deformity (Fig. 173.15). Additional beveling of the defect may be performed if the skin graft is substantially thinner than the depth of the recipient site.

A template is made of the recipient site by outlining the periphery of the wound with a surgical marker and pressing a nonadherent dressing pad over the marking. If the defect is round, the shape is often modified by excising skin to create angulated borders, which improves the contour outcome. In addition, movement and transfer of adjacent facial skin are performed if this is found helpful in isolating the defect to a single facial aesthetic unit. Using the template,

Figure 173.15 Cutaneous graft. A patient status post glabellar flap prior to presenting to our facility. **A:** Open nasal defect following Mohs excision of skin cancer—no nasal laxity; **(B)** preauricular donor site delineated;

Optimize vascularity of wound bed.

the configuration of the graft is determined. The graft is excised and all subcutaneous tissue is removed using curved scissors. This is best accomplished by placing the graft over one's finger, epidermal side down, and trimming off excess fat until shiny dermis is visible (Table 173.13).

The graft is transferred to the recipient site and secured with absorbable sutures as well as a bolster. The bolster is removed after 5 days, and any type of shearing motion is avoided as it may disrupt vascularization of the graft. After removal of the bolster, the patient is instructed to keep the graft dry and apply topical ointment to the graft's edges only. A week or two later, when the graft has survived and is well adhered to the recipient site, the patient is allowed to bathe the area.

The graft may appear bruised during the first few days following transfer. It then transitions to a hyperemic stage, which fades over weeks to months. Occasionally, a dark graft may not survive. If the entire graft dies, it will separate from the recipient site within several weeks. More commonly, the deeper portion of the graft will survive while the more superficial portion forms an eschar, which remains fixed to the wound bed. When this occurs, reepithelialization will occur from the wound edges and from the viable deeper dermal component of the graft. Often, sufficient dermis survives to prevent the development of a depressed scar following complete healing; however, color and textural differences between facial skin and the graft are usually more apparent than when the graft survives completely.

Adjunctive procedures to optimize aesthetic appearance may be performed after grafting. Trapdoor deformities usually resolve overtime with appropriate massage. Grafts rarely require a surgical contouring procedure, but sometimes, Z-plasties may be performed at the border of the graft to enhance the transition between graft and native facial skin. Resurfacing procedures for full-thickness skin grafts are an option, and usually most of the facial skin within the aesthetic units surrounding the graft is resurfaced as well.

Facial Composite Grafts

Composite grafts contain two or more tissue layers and often are unsuccessful secondary to high metabolic demands. They obtain their nourishment through plasma imbibition during the first 24 hours after transfer, followed by vascular inosculation. Ingrowth of capillaries from the edges of the graft begins by the third day (38,39,40).

Composite grafts were first described by Konig (41), who used composite auricular grafts to repair alar defects, noting a 53% graft survival. Composite grafts have been used to repair nasal columellar defects (42,43) and deficiencies in nasal lining (44). During the first half of the 20th century, Limberg (45) advocated the cavum and cymba of the concha as the preferred donor site for repair of the nose. Symonds and Crikelair (46) also used composite auricular grafts for nasal reconstruction, reporting an 89% graft survival rate.

The auricle is an excellent source for composite grafts for facial reconstruction, especially for nasal defects, because it provides a contoured graft of skin and cartilage. Certain segments of the auricle loosely replicate the delicate topography of the columella, facet, and nostril margin where composite grafts are commonly employed. For both anatomic sites, the skin is tightly adherent to the underlying cartilage and/or fibrofatty tissue. Common auricular donor sites are helical crus, helical rim, antitragus, and fossa triangularis. The helical crus provides a good contour match for small alar rim defects and provides the option of incorporating in the graft a segment of preauricular skin.

The traditional recommendation is to limit the size of composite grafts to 1 cm or less (47). Considerably larger grafts may be successful if they are placed in a vascular recipient site and the graft is designed so that no portion is more than 1.0 cm from a wound edge (48–50). Skouge advocated a tongue and groove technique when using composite grafts. This technique involves insetting the border of the graft between two layers of tissue at the recipient site (37). This method of graft attachment has the effect of increasing surface contact between graft and recipient site by 50% (51). A hinge flap developed at the recipient site also increases the surface area for attaching a composite graft (52).

The use of perioperative corticosteroids is beneficial in enhancing survival of composite grafts in animals. Rabbits treated with preoperative and postoperative methylprednisolone demonstrated improved graft survival compared to animals receiving no steroids or postoperative doses only. Attempts to salvage compromised grafts with delayed administration of steroids were not successful (53,54). Cooling of composite grafts has also been demonstrated to improve survival. Cooling reduces biologic requirements and improves graft survival in irradiated, atrophic, or scarred recipient sites. Conley demonstrated that constant application of ice compresses for 14 days effected a fall in skin temperature from 38°F to 17°F. Grafts ranged in size from 1 × 1 cm to 2 × 2 cm. Of twelve composite grafts transferred to the nose and treated with ice compresses, ten survived completely. Five of the grafts had been placed in recipient sites with scarring or postirradiation fibrosis (55).

An ideal defect for a composite auricular graft is a small (1.0 cm or less) full-thickness defect of the nasal facet or columella. The nasal skin in these areas is extremely thin, lacking subcutaneous fat, and is tightly adherent to the underlying cartilage or fibrous connective tissue. Composite auricular grafts obtained from the helical crus provide grafts with thin skin attached to a delicate segment of cartilage, providing structural support and skin that closely resembles the adjacent nasal skin of the columella and facet.

Perhaps more commonly, composite grafts are used to repair small defects of the nasal ala, especially those extending to the alar rim. Composite grafts can be used to maintain structural integrity at the nasal valve and provide a smooth continuous border to the alar rim. Weisberg and Becker describe the use of auricular composite grafts with stabilizing struts for repair of such defects. The stabilizing struts are extensions of cartilage that are placed beneath the adjacent nasal skin in a tongue and groove fashion similar to Skouge's original description (56).

Technique—Facial Composite Grafts

Patient selection is an important consideration. The use of composite grafts is generally limited to small defects in patients who do not use tobacco and have no systemic illnesses that would compromise graft revascularization. Patients receive antibiotics and wound preparation similar to that described when performing skin grafts. In addition, prednisone is administered on the day of surgery and a steroid taper is provided postoperatively.

Improved survival rate is noted if grafting is delayed until the facial defect has partially healed by secondary intention. The facial defect is then prepared by removing any epithelium and subepithelial scar tissue, and a template is created that measures several millimeters larger than the defect in all dimensions. Harvesting a graft that is slightly larger than the defect accommodates for the inevitable contraction of the graft. Whenever possible, a flap of soft tissue hinged on a border of the defect is developed to enhance surface contact with the graft. A composite graft containing skin and cartilage is harvested from the region of the auricle that most closely matches the contour and thickness of the nose at the defect site. The graft is placed in cold saline, and the donor site is closed primarily using polydioxanone or poliglecaprone sutures to approximate the edges of the auricular cartilage and polypropylene sutures for the skin. The graft is transferred to the recipient site and secured in place with simple absorbable sutures, limiting the degree of manipulation of the graft. If the graft is small, no sutures are placed through the cartilage. Limiting the number of sutures used to fix the graft in place is thought to be beneficial in enabling earlier and more abundant vessel ingrowth.

Ice–saline compresses are applied for the first 3 to 5 days. Successful grafts transition in color during the first week: blanched at initial transfer, pink color at 6 hours, darker by 24 hours, and gradual development of a pink color in 3 to 7 days. Complications include partial or complete graft loss, contracture, pigmentary changes, and contour abnormalities. Contour abnormalities may be addressed with a debulking or scar revision procedures.

COMPLICATIONS

It is essential that surgeons become familiar with the potential complications associated with facial reconstructive surgery, anticipating these undesirable events and taking proper measures to help prevent their occurrence (Table 173.14). Establishing a consistent perioperative routine is the first step in preventing complications. Appropriate preoperative counseling of the patient will reduce the likelihood of complications, and informed consent should include an open discussion of potential problems that may occur. Immediate and regular postoperative evaluations of the patient will facilitate early recognition and treatment of complications. Some complications are reversible, and expeditious treatment may prevent a reversible complication from becoming an irreversible one. Finally, adherence to well-established surgical principles is essential for minimizing the incidence of complications when performing facial reconstructive surgery.

Bleeding

Common causes of bleeding from facial reconstruction using local flaps are drug-associated coagulopathy and inadequate hemostasis. Patients are questioned preoperatively concerning use of all prescription and over-the-counter medications that may contribute to perioperative bleeding. Discontinuation of any medications prescribed by a physician to reduce blood clotting is coordinated with the patient's medical physician or cardiovascular specialist. Bleeding may also be associated with hypertensive events, hepatic or renal failure, vomiting, straining, or alterations in the hematopoietic system.

Hemostasis is essential. Bipolar electrocoagulation is used to control bleeding from smaller vessels and larger arterial vessels are securely ligated when interrupted. Drains are rarely used with local cutaneous flaps, with the exception of extensive cervicofacial flaps or ear reconstruction.

TABLE 173.14 COMPLICATIONS LOCAL CUTANEOUS FLAPS AND GRAFTS

Distortion of facial features and boundaries

However, an appropriately sized drain is employed when a significant "potential space" is present or drainage is expected that cannot be controlled with a compression dressing. A compression dressing that conforms to the anatomical contour of the surgical site to facilitate adherence of the facial flap to the recipient site is typically left in place for 48 hours. The dressing consists of nonadherent gauze, cotton balls, and expandable mesh tape. Patients are instructed to keep their head elevated, especially at night, for the first 48 hours after surgery, and coughing and straining are to be avoided whenever possible.

Hematomas may cause compromise of local flap vascularity by inducing vasospasm, stretching the subdermal plexus, or separating the flap from the surface of the recipient site (57–59). Furthermore, iron compounds in a hematoma may promote free radical production leading to flap necrosis (60,61). Hematoma formation also predisposes to infection, which may compromise flap vascularity secondary to inflammatory edema (62,63).

If a hematoma occurs, patients usually complain of significant pain. The wound may appear mottled, pale, or bluish, and palpation of the skin in the area of the hematoma usually reveals a tight, tense flap with oozing of blood from the suture lines. Small hematomas may sometimes be aspirated through the suture line using a syringe attached to a large-bore needle. A compression dressing is then applied and the patient is reexamined in 24 hours. If the hematoma recurs, it may be necessary to return the patient to the operating room for thorough drainage and irrigation. In that setting, the wound is opened at a dependent portion, the hematoma is evacuated, bleeding vessels are controlled, and irrigation is performed. A compression dressing is reapplied with the patient being admitted or examined in clinic within 24 hours.

Infection

Fortunately, infection during facial surgery is reported to be as low at 2.8%, perhaps secondary to the rich vascularity of facial tissues (64–67). However, higher infection rates are associated with wounds that are repaired in a delayed fashion, as is often the case with facial flaps used to repair wounds created by Mohs surgery (66,68,69). Infection of a cutaneous flap is usually associated with distortion from inflammatory edema. Release of toxic substances and free radicals from inflammatory mediators leads to decreased collagen production and early degradation of suture materials with potential wound dehiscence. Necrosis of all or part of the flap may develop with the final scar being widened or thickened. Systemic dissemination of bacteria may occur if wound infections are not treated promptly (70,71).

Antiseptic solutions for skin preparation, sterile technique, proper scrubbing, and surgical attire are key elements in helping prevent infection. Avoiding crushed, charred, or excessively thinned tissue is also important. Staphylococcus aureus is the most common single pathogen causing wound infections, but streptococci, gram-negative bacteria, and oral anaerobes may also be isolated from infected wounds (68). Antibiotics are particularly helpful when mucosal surfaces are incised, when cartilage grafting is performed, and during ear reconstruction to help prevent perichondritis. They are also employed in patients with underlying medical conditions that may predispose to infection such as diabetes and immunosuppression. In patients with open wounds greater than 3 days old, a 5-day course of oral cephalosporin is recommended prior to the surgical repair. This will decrease the bacterial colonization of the granulation tissue that may lead to graft or flap failure.

If a wound infection does develop, Gram stain and cultures of any drainage from the wound are obtained. The patient is treated with an appropriate broad-spectrum antibiotic until culture results and sensitivities are available. Any wound fluctuance is drained and the wound irrigated. The presence of excessive granulation tissue may require debridement to reduce the bacterial load. Topical antibiotic preparations may also be employed, and superficial sutures are removed to eliminate foreign bodies in the wound (72). Open wounds are allowed to heal by secondary intention. The resulting scar is addressed at a later time once the infection has been adequately treated and scarring has matured.

It is important to remember that topical allergies to antibiotic ointments and creams applied to the wound may be confused with wound infection. Topical allergic reactions manifest as erythema often with vesicle formation and exudates forming on all areas treated with the topical medication. The offending agent should be discontinued and the wound cleaned with soap and water in order to remove all residual topical medication.

Injury of Adjacent Anatomical Structures

A thorough understanding and appreciation of facial anatomy is a crucial prerequisite for performing facial reconstructive procedures, and general considerations related to protecting adjacent anatomical structures should be reviewed.

Perhaps one of the most devastating complications associated with facial surgery is injury to the facial nerve or one of its branches. Although rare, extensive dissection in the preauricular area could lead to injury to the main branch of the facial nerve. More commonly, the marginal mandibular or temporal branches of the facial nerve are injured. Familiarity with cross-sectional anatomy of the temple and mandibular regions is essential prior to surgical dissection in these areas. Sensory nerves are also susceptible to injury during facial reconstructive procedures. Extensive undermining along the superior bony orbital rim may injure the supraorbital or supratrochlear nerves leading to dysesthesias (73). Similarly, the deep branch of the supraorbital nerve runs within the galea aponeurotica and may be injured when undermining the frontalis muscle in the subgaleal plane. The great auricular nerve may be

injured during subcutaneous dissection, and this nerve is identified and preserved when dissecting skin away from its attachment to the superior aspect of the sternocleidomastoid muscle.

Avoiding injury to the nasal cartilaginous framework is important for maintaining nasal symmetry and function. Inadvertent injury to these structures may lead to obvious nasal deformities including alar retraction, nasal valve collapse, and saddle nose deformity. Occasionally, preexisting structural abnormalities of the nose are corrected during reconstructive surgery of the nose, when the exposure of the nasal framework is sufficient, allowing potential improvement in aesthetic and functional outcomes. Preexisting weaknesses in the nasal structural support system may become more pronounced when cutaneous flaps are mobilized, especially when skin tension is increased across a weakened framework.

Injury to eyelid structures may lead to devastating consequences, including lagophthalmos, lacrimal duct obstruction, visual field obstruction, and vision loss. Facial surgeons should be familiar with the cross-sectional anatomy of the upper and lower eyelids, especially the connective tissue supportive apparatus. Injury to these structures is best avoided, since treatment is extremely difficult if scarring has occurred (70).

Wound Dehiscence

Wound dehiscence may develop secondary to infection, hematoma, or skin necrosis. In addition, dynamic motion or trauma to wounds may also lead to wound separation. Typically, wounds have 3% to 5% of normal skin tensile strength at 2 weeks after surgery, emphasizing the need for subcutaneous sutures. At 1 month, only 35% of the maximum wound tensile strength has been gained. However, at this point, the wound is usually able to withstand the forces of normal physical activity. Over the succeeding months, wound tensile strength increases to 80% of the strength of normal tissue. Wound separations that have been present for greater than 24 hours are best left to heal by secondary intention with scar revision reserved for the future if necessary (71,74).

Ischemia

Appropriate flap design is essential to ensure sufficient perfusion pressure of the entire flap (75). Random-pattern flaps require an intact subdermal plexus, and dissection is performed in the appropriate subcutaneous tissue plane since superficial dissection may lead to compromise of the flap's vascularity. Random-pattern flaps have a critical length beyond which the perfusion of the distal flap does not occur. Although increasing the width of a flap's pedicle potentially increases the number of vessels contained in the subdermal plexus of the flap, it does not increase the perfusion pressure to the distal portion of the flap.

Design of axial pattern flaps requires a thorough knowledge of the location and orientation of the arterial vessels supplying the skin in order to properly align the flap with the axis of the artery and to avoid inadvertent injury to the flap's blood supply. Increasing the width of the pedicle of axial flaps does not necessarily improve perfusion (76,77). Often, it is more advantageous to raise a thicker flap that contains deeper subcutaneous vessels than design the flap with a wider base.

Ischemia is defined as vascular perfusion insufficient to provide the required oxygenation of tissue (72). Cutaneous flaps are more vulnerable to tissue ischemia than wounds closed primarily given that the vascularity is isolated to the pedicle of the flap used for repair of the wound (78). This is especially true in the distal portion of the flap (28,79). Dissection of flaps causes release of catecholamines from severed sympathetic nerves, thromboxane A from platelet microthrombi, and oxygen free radicals. All of these substances cause vasoconstriction that can enhance tissue ischemia (80,81). Excessive flap thinning, electrocautery, crush injury, and wound closure tension may worsen flap ischemia. Infection is treated expeditiously since edema from inflammation may decrease tissue perfusion. When flap ischemia is evident, local wound factors and factors related to the patient are assessed and medical conditions optimized as discussed previously. In such situations, use of nicotine by the patient must be avoided.

Arterial insufficiency of a flap may be caused by kinking of the flap's pedicle, an excessively tight compression dressing or excessive wound closure tension. If these causative factors are corrected early in the postoperative period, the ischemia is usually reversible. In the case of excessive wound closure tension, sutures may be removed and/or the flap may be returned to its donor site, thereby delaying the flap that may improve blood supply to allow later transfer of the flap to the recipient site. When ischemia causes epidermolysis or skin necrosis, the tissue is allowed to demarcate since the more proximal portion of the flap is usually viable. Patients are instructed to keep the wound moist with petroleum- or water-based antibiotic ointment while the wound is allowed to heal by secondary intention. Frequent follow-up examination is essential for maintaining appropriate wound care, including wound debridement, and for providing reassurance to the patient.

Abnormal Scarring

Patients with darker skin and those with a family history of excessive scarring are prone to the development of hypertrophic scars and keloids following surgery. Intralesional triamcinolone acetonide is often helpful in reducing the volume of scar tissue within a hypertrophic or keloid scar. Injections are used to soften firm scars, lower raised keloids, and prevent their recurrence. Steroids decrease fibroblast proliferation, reduce blood vessel formation, and interfere with fibrosis by inhibiting extracellular matrix protein gene expression. Excessive steroid injection of scars may lead to skin atrophy, hypopigmentation, and telangiectasias. If the scar is responsive to the injections, surgical excision may be performed following a preoperative injection 1 week prior

to surgery. Several injections are usually required postoperatively after excision for an indeterminate time interval.

Scars continue to change and improve during the remodeling phase of wound healing. Younger patients may have an exaggerated and prolonged healing reaction with increased scar erythema and hypertrophy, so scar revisions in children should be delayed as long as feasible. Immature scars tend to be erythematous, which will usually fade over time. Wounds subjected to excessive wound closure tension may result in scars that are hypopigmented and often hypertrophied. Incisions made in thick skin, especially if there is sebaceous gland hypertrophy, may heal with depressed or widened scars. Scar hyperpigmentation may be seen in patients who tan easily, particularly if the patient is exposed to excessive sun exposure during the immediate postoperative period. Hyperpigmentation improves over time and with sun avoidance. Use of topical hydroquinone gel with or without the administration of an anti-inflammatory drug may be helpful in preventing permanent discoloration of the scar (70).

Trapdoor Deformity

Trapdoor deformity may result from persistent edema and poor lymphatic drainage of flaps with curvilinear borders since the scar around the border of the flap contracts in a concentric fashion (82–84). Bilobed flaps of the nasal skin are particularly susceptible to trapdoor deformity because of the two circular lobes used for construction of the flap, especially when the nasal skin is thick and has sebaceous gland hypertrophy. Patient selection, proper flap design, and adequate tissue undermining reduce the incidence of trapdoor deformity. Presumably wide undermining reduces scar contractile vectors toward the center of the flap by enlarging the area of the underlying sheet of scar (82–84). Flaps that are superiorly based are more prone to develop trapdoor deformity than inferiorly based flaps, likely because lymphatic channels of the face drain in an inferior direction.

Trapdoor deformity usually improves with time. Steroid injections into the subcutaneous tissue plane beneath the flap may be performed using triamcinolone acetonide (10 mg/mL). If time and steroid injections are not successful, contouring of the flap with or without scar revision is necessary. This involves debulking of subcutaneous fat and scar tissue beneath the flap and redraping the skin. Excess skin is trimmed as indicated, and Z-plasties performed along the incision may be helpful in preventing recurrence.

Distortion of Facial Features and Boundaries

Scar contracture and excessive wound closure tension may lead to poor aesthetic and functional outcomes, especially in regions of the face with mobile facial structures such as the eyelids, lips, and nasal alae. This is especially problematic in the periocular and oral area where inadequate lip or eyelid closure leads to problems with eating, phonation, excessive tearing, and dry eye symptoms. Cervical facial flaps used to repair cutaneous defects near the lower eyelids should be secured to the periosteum of the maxilla or nasal bones using a tacking suture in order to help prevent eyelid retraction secondary to excessive wound closure tension. A temporary Frost suture may also be used to limit the downward pull of the flap on the eyelid skin.

Flaps used for repair of the nose are designed sufficiently large to avoid alar retraction. For defects adjacent to the alar rim, cartilage grafting can be employed to provide a strut against the contractive forces of wound healing. The lip is also vulnerable to distortion by scars because of the mobile nature of the lips and the discreet borderline between the skin and vermilion. During healing, vertically oriented scars of the upper lip require only minimal contraction to cause notching or distortion of the vermiliocutaneous border. Such distortion is quite noticeable to the observer particularly when the vermilion is well developed. In addition to limiting wound closure tension as much as possible, precise alignment of the opposing edges of the lip wound in the vicinity of the vermiliocutaneous borders is extremely important when repairing lacerations or cutaneous defects of the lip.

Standing cutaneous deformities result from transfer of cutaneous tissue with unequal wound borders. In the majority of cases, these deformities may be safely excised at the time of wound repair. Swelling may prevent an accurate estimate of the size of the deformity and lead to a persistent standing cutaneous deformity.

It is important to respect the borders of facial aesthetic regions and units when designing cutaneous flaps in order to avoid unsightly scars. This is particularly true of the alar facial sulcus, which is an important boundary between the aesthetic regions of the nose, cheek, and upper lip. Larger defects of the ala are best reconstructed with interpolated cheek flaps that cross over the alar facial sulcus rather than using transposition or advancement cheek flaps that would obliterate this aesthetic boundary line. Cutaneous defects that extend from the nose to the medial cheek or to the upper lip are best repaired using separate flaps for each aesthetic region. This approach positions the borders of the flaps in aesthetic boundary lines that help camouflage scars and preserve the concave topography of the alar facial sulcus (70).

HIGHLIGHTS

- Skin is characterized as being directional or anisotropic, with a nonlinear stress–strain relationship.
- Delay of a cutaneous flap is thought to improve survival and is particularly helpful in patients with a history of radiation or tobacco smoking.
- Analysis of a facial defect includes determining the depth, size, and location of the wound. In addition, the color, texture, laxity, and thickness of adjacent skin should be assessed.

- Facial cutaneous flaps can be classified based on (a) location, (b) vascular supply, and/or (c) flap design and method of tissue movement.
- Examples of pivotal flaps include rotation, transposition, and interpolation flaps, and longer flaps may be required to account for loss of effective length with greater degrees of pivotal movement.
- Advancement flaps are most successful in areas of greatest tissue laxity and extensibility.
- Full-thickness cutaneous grafts have the advantage over split-thickness grafts of better color and texture match, less contour irregularities, little need for special equipment, and easier donor site wound care.
- Composite grafts contain two or more tissue layers and often are unsuccessful secondary to high metabolic demands.
- Complications of facial cutaneous flaps and grafts include bleeding, infection, injury of adjacent anatomical structures, wound dehiscence, ischemia, abnormal scarring, trapdoor deformity, and distortion of facial features and boundaries.

174 Reconstructive Microsurgery of the Head and Neck

Douglas B. Chepeha

Microvascular free tissue transfer was introduced as a technique that enabled reconstruction of defects that could not otherwise be reconstructed. The viability of autogenous transplants and the long operating time were initial concerns. During the 1980s, use of regional pedicled flaps (pectoralis, trapezius, latissimus dorsi) overshadowed microvascular free tissue transfer. Regional flaps were technically much easier, required only one surgical team, and supplied nonirradiated tissue. Microvascular reconstruction continued to evolve. More donor sites were described each year, and the versatility of each site was explored and expanded. More surgeons were trained in microvascular techniques, and these surgeons became increasingly adept. As the practice of reconstructive microsurgery became more common, the success rate improved (95% to 98%), and the operative time decreased (1,2).

Controversy still exists about whether microvascular reconstruction is functionally superior to pedicled reconstruction of comparable defects. Intuition suggests that revascularized free tissue transfer is functionally superior because it allows the reconstructive surgeon to customize reconstruction of defects of the head and neck. Autogenous transplants can be designed to provide epithelium, subcutaneous tissue, muscle, nerve, and bone in proportions that closely resemble the missing tissue.

If autogenous transplantation is functionally superior, is it cost-effective? Several studies have suggested that use of pectoralis flaps is associated with longer hospital stays and higher complication rates than free tissue transfer in comparable primary reconstructions (3–5). This suggests that the costs of longer operating times associated with free autogenous transplantation may be offset by the longer hospitalizations associated with pedicled transfer.

The drive for reconstructive surgeons to provide the best functional and aesthetic reconstruction for their patients made autogenous transplantation the mainstay of head and neck reconstruction in the 1990s. In the last 10 years, more donor sites are used, more transfers are performed, perforator-based chimeric elevations are increasing reconstructive options, indications have broadened, and operating time has been reduced (6). More research is being conducted to establish the value and exact place of these sophisticated reconstructive techniques in the various defects encountered in the head and neck.

This chapter is divided into two sections. The first section is an introduction to free tissue transfers commonly used in head and neck reconstruction (Table 174.1). Each flap is described in terms of design and use, anatomic characteristics, anatomic variations, potential morbidity, technical considerations, preoperative considerations, and postoperative management. The second section is an introduction to commonly encountered defects of the head and neck.

FASCIAL AND FASCIOCUTANEOUS AUTOGENOUS TRANSPLANTS

Radial Forearm Donor Site

Description

The radial forearm is a fasciocutaneous donor site comprised of thin skin and subcutaneous tissue based on the radial artery and its venae comitantes and the cephalic vein (Fig. 174.1). This site can be transferred as a composite transplant that contains vascularized bone, vascularized tendon, the brachioradialis muscle, and vascularized nerve. The skin of the entire forearm, from the antecubital fossa to the flexor crease of the wrist, can be transferred. The vascular pedicle can be as long as 20 cm, and the artery is 2 to 2.5 mm in diameter. The radial forearm donor site contains axial nerve supply useful for sensory reinnervation. It can be used to reconstruct small (less than 60 cm) to moderate surface area (less than 200 cm^2) defects and is a low-volume donor site. The tissue for this donor site can be folded to facilitate sophisticated reconstructions. Because

TABLE 174.1 MICROVASCULAR FREE SOFT TISSUE FLAP SELECTION IN HEAD AND NECK RECONSTRUCTION

Flap	Quality	Advantages	Disadvantages
Radial forearm	Thin, pliable	Versatility, ease	Limited bulk, skin graft donor site
Lateral arm	Moderately thin	Primary closure of donor site	Small-caliber pedicle
Lateral thigh	Moderately thick	Large surface area of tissue, long pedicle	Challenging harvest
Anterolateral thigh	Thin, pliable	Long pedicle, large cutaneous component, chimeric options	Variable anatomy
Temporoparietal	Ultrathin	Can be transferred as pedicle flap	Challenging harvest, limited pedicle length, scalp skin is stiff
Rectus	Bulky	Versatility, ease of harvest, chimeric options	Risk of ventral hernia
Latissimus dorsi	Moderate bulk	Large surface area, ease of harvest	Lateral decubitus position
Gracilis	Thin muscle	Can be separated into functional units	Limited tissue available

of the increasing use of the anterolateral thigh donor site for larger defects, the radial forearm donor site is most commonly used for the reconstruction of smaller defects of the oral cavity (including central hard palate, base of the tongue, soft palate) and partial and circumferential reconstruction of the pharynx. It also can be used to manage cutaneous defects of the eye, lip, neck, and scalp. When elevated as a fascial paddle (no cutaneous component), the radial forearm donor site can be used to manage soft tissue defects and defects of the base of the skull particularly for

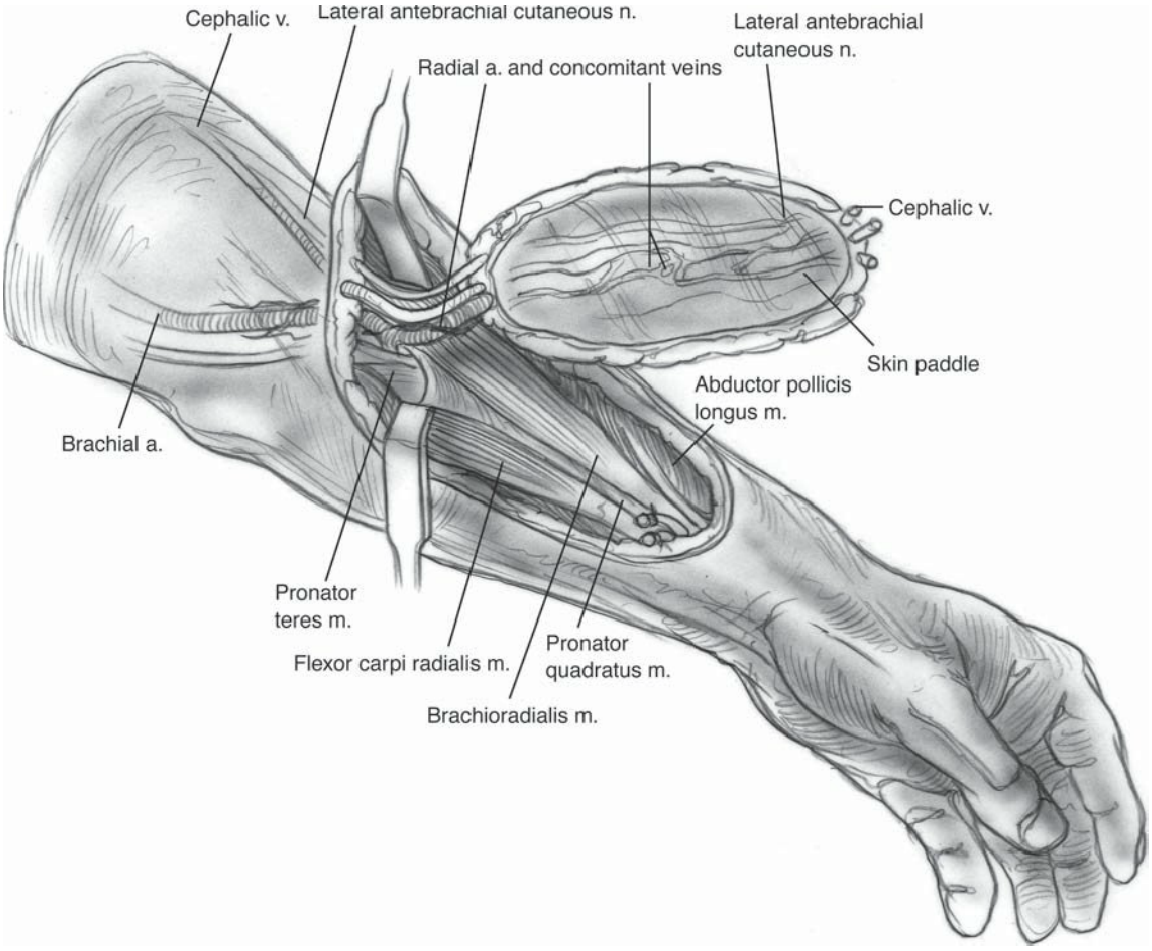

Figure 174.1 Lateral view shows left lateral forearm. The flap axis is slightly medial to the radial artery, and the flap is positioned to include the cephalic vein over the extensor compartment. Nutrient branches to the radius are immediately deep to the brachioradialis tendon. The superficial branch of the radial nerve is preserved in dissection of this flap.

a previously treated patient when local pericranial flaps are not available (7). When this donor site is elevated as an osteocutaneous flap, a segment of radius 10 to 12 cm long and as much as 40% of its circumference can be harvested with overlying fascia and skin (8). In the past, this donor site was useful for reconstruction of small-volume bone and soft tissue defects of the face, such as the periorbital tissues, particularly if the patient has undergone or is to undergo radiation therapy (9), but the thoracodorsal artery scapular tip (TDAST) has nearly replaced the use of the radial forearm donor site for patients with these mid and upper craniofacial defects. Another use of vascularized radial bone is for the prevention of plate exposure for patients who have undergone lateral mandibular resections and have low to moderate loading of the mandible (8). The disadvantage of the radial osteocutaneous transplant is the limited amount of donor bone and the risk of pathologic fracture of the radius.

Neurovascular Pedicle

The radial artery, with its two venae comitantes, courses in the lateral intermuscular septum and has several fascial branches in the forearm (10). This fascial plexus supplies most of the skin in the forearm. The length of the arterial pedicle is limited by the radial recurrent artery, which is the first major branch of the radial artery after its takeoff from the brachial artery. The site has a deep venous drainage through the paired venae comitantes and the larger superficial veins, such as the cephalic vein. Numerous connections exist between the venae comitantes and the superficial venous system; these vessels provide excellent venous drainage of this donor site. If necessary, and if proper testing of the venous drainage of this donor site is conducted after elevation, it usually is possible to drain the flap through the superficial system alone. It is nearly always possible to drain this donor site through the venae comitantes alone. The lateral antebrachial cutaneous nerve is the primary sensory nerve to the territory of forearm skin most commonly harvested. This nerve typically courses close to the cephalic vein in the upper forearm. When sensory reinnervation is needed, this nerve can be easily anastomosed to a recipient sensory nerve.

Anatomic Variations

The greatest concern during harvest of the radial forearm donor site is the integrity of the ulnar arterial supply to the hand through the palmar arches. The combination of two concurrent arterial variations, an incomplete superficial palmar arch and a lack of communication between the superficial and deep palmar arches, puts the vascular supply of the thumb and index finger in jeopardy (11). This anomaly can be detected with an Allen test. This test involves assessment of capillary refill of the thumb and index finger with the radial artery occluded. The patient is asked to clench his or her fist. The examiner uses digital pressure to occlude the radial and ulnar arteries at the wrist. The patient opens the hand to approximately 10 degrees of flexion, the examiner releases the ulnar artery, and capillary refill is assessed. If there is uncertainty about digital blood flow during capillary refill assessment, Doppler assessment of the digital artery is performed to the thumb, and the results are definitive.

Potential Morbidity

Often the donor site cannot be closed primarily, and a skin graft is necessary, which can be unsightly. Poor take of the skin graft can be caused by inadequate immobilization of the hand or failure to preserve the paratenon over the flexor tendons. Radial osteocutaneous flaps are limited by risk of fracture of the radius and a detrimental effect on supination, wrist flexion, grip strength, and pinch strength (12). A plate can be applied to the radius bone to reduce the likelihood of radial fracture for osseocutaneous elevations (13).

Technical Considerations

The design of a radial forearm skin paddle begins with an outline of the path of the dominant subcutaneous veins and the palpable pulse of the radial artery. The skin paddle is oriented over the radial artery and cephalic vein. It is preferable not to perform the elevation over the ulnar artery. Additional subcutaneous tissue can be incorporated when needed, from the brachial fat pad, to increase the volume of the transplant. During harvest, the paratenon over the flexor tendons is preserved to facilitate skin graft healing. If necessary, the flexor tendons can be covered with turnover muscle flaps to improve the donor-site bed for skin grafting.

Preoperative Considerations

Accurate performance of an Allen test is the most important consideration in avoiding ischemia of the hand. When the Allen test results are equivocal, the opposite hand or an alternative donor site should be selected.

Postoperative Management

The forearm donor site and wrist are immobilized with a volar splint with the wrist in the position of function for 6 to 7 days. Then a removable volar plastic splint is used for an additional 3 to 5 weeks until the skin graft is healed over the donor site. After an osseocutaneous flap, the elbow and wrist are immobilized with a full arm cast with the hand in the position of function. This cast is left on for 4 weeks, then the wrist is immobilized with a forearm cast, and this is left on for an additional 2 weeks. The patient is encouraged to use the arm throughout the casting period. The underlying philosophy is to allow time for reshaping of the load lines in the radial bone. Any limb with circumferential dressing needs to be closely observed in the immediate postoperative period for signs of vascular insufficiency.

Lateral Arm Donor Site

Description

The lateral arm is a fasciocutaneous donor site that is usually thicker than the radial forearm donor site, the vascular

pedicle is based on the posterior radial collateral artery and its venae comitantes, and it can be reinnervated for cutaneous sensation with the posterior cutaneous nerve of the arm (14). The donor site usually can be closed primarily when the width of harvested skin is limited to 6 to 8 cm, or one-third the circumference of the arm. Larger skin paddles can be harvested, but a skin graft will be required over the donor site. The donor site can be harvested as a fascial flap and is a good source of vascularized tissue for augmentation of subcutaneous defects caused by lateral temporal bone resection or total parotidectomy (15). The donor site can include the posterior cutaneous nerve of the forearm for use as a vascularized nerve graft, but more frequently the nerve is dissected out of the skin paddle and used as a free nerve graft because it may not be possible to properly orient the nerve and vascular pedicle when insetting. The clinical usage of the lateral arm donor site is affected by the body mass index (BMI) of the patient. In patients with a lower BMI, the lateral arm can be used for low-volume oral cavity, low-volume oropharyngeal, and low-volume cutaneous defects particularly when slightly more volume is required than the forearm donor site can provide. In patients with higher BMI, the lateral arm donor site can be used for higher-volume base of tongue, lateral oropharynx including the parapharyngeal space, anterior oral glossectomy, lateral temporal bone, and parotid and midfacial defects (16). The thickness of the skin paddle can be varied with placement because the skin over the lateral epicondyle is much thinner than the skin over the lower and mid upper arm. When estimating volume, it is important to remember that the subcutaneous tissue over the deltoid is more prone to long-term atrophy than the subcutaneous tissue over the mid lateral arm. Many of the applications of the lateral arm flap have been supplanted by the perforator-based anterolateral thigh donor site due to its larger, longer pedicle and ease of primary closure.

Neurovascular Pedicle

The vascular supply of the lateral arm skin paddle is based on the terminal branch of the profunda brachii artery and the posterior radial collateral artery and its venae comitantes. The blood supply to the skin is derived from four to five septocutaneous perforators that arise from the posterior radial collateral artery in the lateral intermuscular septum. In the region of the deltoid insertion, where the posterior radial collateral artery enters the lateral intermuscular septum, the artery has an average diameter of 1.55 mm (range, 1.25 to 1.75 mm) and a maximum pedicle length with additional dissection of 8 to 10 cm (17). Additional pedicle length and caliber can be obtained by means of extending the dissection proximally between the lateral and long heads of the triceps muscle. The muscular branches from the radial nerve to the triceps muscle must be identified and preserved when this approach is used. In practice, it is difficult to obtain more than 4 cm of pedicle length by using this proximal dissection technique without detaching a large amount of triceps and dividing the motor branches to the triceps muscle. To accommodate the fairly short pedicle, the skin paddle can be moved to a more distal location over the lateral epicondyle. This maneuver results in a thinner skin paddle. A second superficial venous system incorporates the cephalic vein, but is rarely used in practice. Two sensory nerves are encountered during elevation of the skin paddle; each arises from the proximal portion of the radial nerve. The nomenclature of these sensory nerves is confusing. The nerve that supplies sensation to the skin paddle is the posterior cutaneous nerve of the arm (also called the lower lateral cutaneous nerve of the arm and the inferior lateral brachial cutaneous nerve). The posterior cutaneous nerve of the forearm (also called the posterior antebrachial cutaneous nerve) runs through the lateral arm flap to the forearm and can be used as a vascularized nerve graft. Harvest of the skin paddle results in a variable area of cutaneous anesthesia over the mid extensor surface of the forearm.

Anatomic Variations

Unlike the radial forearm donor site, the lateral arm elevation does not affect the circulation to the distal portion of the arm. The profunda brachii artery can be interrupted without ischemic sequelae. The incidence of duplication of the profunda brachii artery ranges from 4% to 12% in different series.

Potential Morbidity

The radial nerve, which lies in the spiral groove of the humerus, is identified and protected from injury during flap harvest. Postoperative radial nerve palsy has been attributed to constrictive dressings or tight wound closure. Use of split-thickness skin grafts is preferable to tight primary closure.

Technical Considerations

The lateral intermuscular septum is approximately 1 cm posterior to a line drawn from the insertion of the deltoid muscle and the lateral epicondyle. The central axis of the skin paddle is based on the intermuscular septum (Fig. 174.2). Closure of the donor site is important for reestablishing coverage of the radial nerve and reattachment of the insertion of the brachialis and brachioradialis muscles. The brachialis muscle is reapproximated to the triceps muscle so that 1 cm of muscle provides coverage of the radial nerve. In addition, the brachioradialis muscle needs to be sutured to the distal triceps muscle, and this is accomplished with the elbow in flexion. Recipient vessel planning is important because of the relatively short pedicle and the small caliber of the donor vessels. For patients undergoing lateral parotid and temporal reconstructions, preservation of the occipital artery as it crosses the internal jugular vein makes recipient vascular access relatively easier.

Preoperative Considerations

The thickness of the flap is assessed by means of palpation. The soft tissue of the donor site thins and becomes

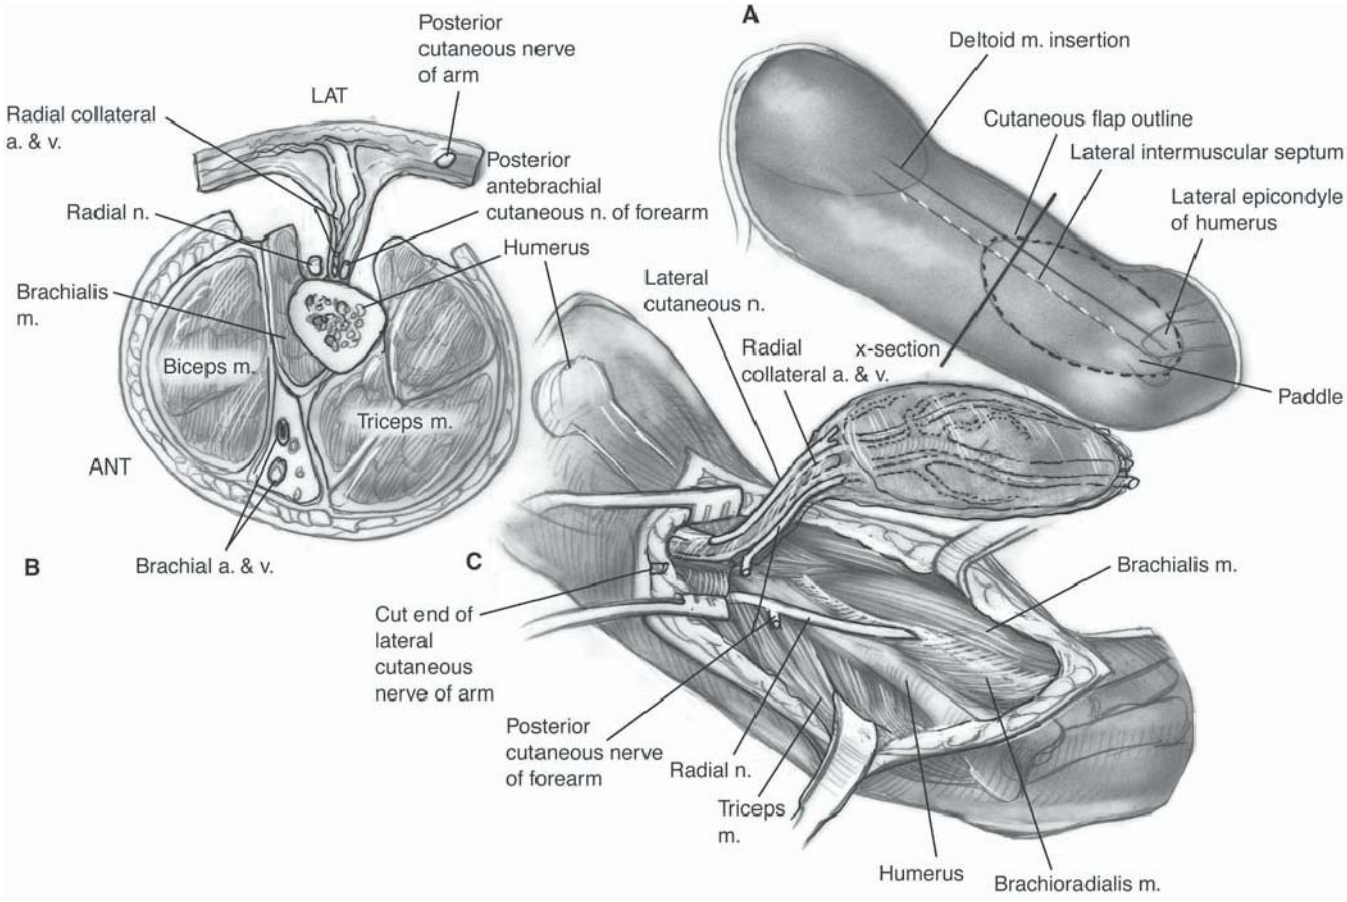

Figure 174.2 **A:** The flap is marked over the lateral epicondyle and 1 cm dorsal to a line drawn from the tip of the deltoid muscle to the lateral epicondyle. This position maximizes pedicle length and centers the flap over the lateral intermuscular septum. **B:** Cross section shows upper arm at the level shown in **(A)**. The lateral arm flap is elevated but still attached by the intermuscular septum to the humerus. At this level the posterior cutaneous nerve of the arm is in the subcutaneous fat, whereas the posterior cutaneous nerve of the forearm still is in the intermuscular septum. **C:** Lateral view shows lateral arm flap with the pedicle still in continuity. The radial nerve crosses the humerus and enters the cleft between the brachialis and the brachioradialis muscles.

more pliable when it is positioned more distally on the upper arm. In general, one-third of the circumference of the upper arm can be harvested. Primary closure can be assessed using a pinch test. It is best to have recipient vessels from a previously undissected neck.

Postoperative Management

A suction drain is recommended. If a skin graft is used, a volar slab is fashioned, the elbow is placed in flexion, and the donor site is managed in a manner similar to the radial forearm donor site.

Lateral Thigh

Description

The lateral thigh donor site was popularized by Hayden (18), who found it useful for pharyngeal reconstruction. For selected patients with favorable body habitus, this donor site provides a large surface area of tissue with an adequate vascular pedicle. Skin paddles as large as 25 × 14 cm have been transferred successfully (19). This fasciocutaneous donor site ranges from thin to moderately thick depending on the patient's body habitus. Sensory reinnervation is possible with the lateral femoral cutaneous nerve. Elevation of this donor site is technically challenging and has been supplanted by the anterolateral thigh donor site, which is technically easier to harvest and has a long vascular pedicle.

Anterolateral Thigh

Description

The anterolateral thigh donor site is a septocutaneous or musculocutaneous flap based on the descending branch of the lateral circumflex femoral artery and associated venae comitantes. The elevation can be designed to include any of the structures supplied by the common pedicle of the lateral femoral circumflex vessels, which can include the tensor fascia lata, the vastus lateralis, and/or the rectus femoris. The skin paddle can be harvested as large as

20 × 15 cm. The skin of the anterolateral thigh is thin and pliable in most males, whereas in females, this flap can be thicker depending on the pattern of fat deposition. The anterolateral thigh donor site has become one of the workhorse donor sites for soft tissue reconstruction in the head and neck. It has many of the same characteristics as a radial forearm donor site, such as thin pliable skin and a long vascular pedicle. The anterolateral donor site is a source for larger skin paddles and more subcutaneous tissue than a radial forearm donor site and, as a result, has been nicknamed its "big brother." The nerves for sensation are the anterior femoral cutaneous and the lateral femoral cutaneous and do not run axially with the pedicle. The applications for this flap include face, neck, full-thickness buccal, hemiglossectomy, subtotal glossectomy, oropharynx, total pharyngeal, and skull base defects (20,21). The donor site is closed primarily when the skin paddle is less than 9 cm in width. The disadvantage is the variable location of the pedicle and the perforators. To overcome this disadvantage and as familiarity with this donor site has increased, more of the elevations are designed around a perforator. The dominant perforator is identified and is dissected retrograde to the lateral circumflex femoral artery. This approach has several advantages: The elevated tissue can easily be centered on the dominant perforator, the underlying muscle is preserved, and the volume of the donor site can be controlled because the surgeon can choose to elevate muscle independent of the variation of the vascular pedicle.

Neurovascular Pedicle

The perforators from the pedicle are located on a line drawn from the anterior superior iliac spine to the lateral edge of the patella and are usually between the midpoint and the junction of the upper and middle thirds of the line. A Doppler probe is used to locate the perforators.

Anatomic Variations

There are four patterns of vascular supply to the skin paddle (22). There are two musculocutaneous types, the vertical musculocutaneous (50%) and the horizontal musculocutaneous (30%), and two septocutaneous types, the vertical septocutaneous (15%) and the horizontal septocutaneous (5%) (Fig. 174.3A and B).

Potential Morbidity

There is little morbidity reported even with harvest of large portions of the vastus lateralis. The vastus lateralis is a stabilizer of the rectus femoris (23). With more

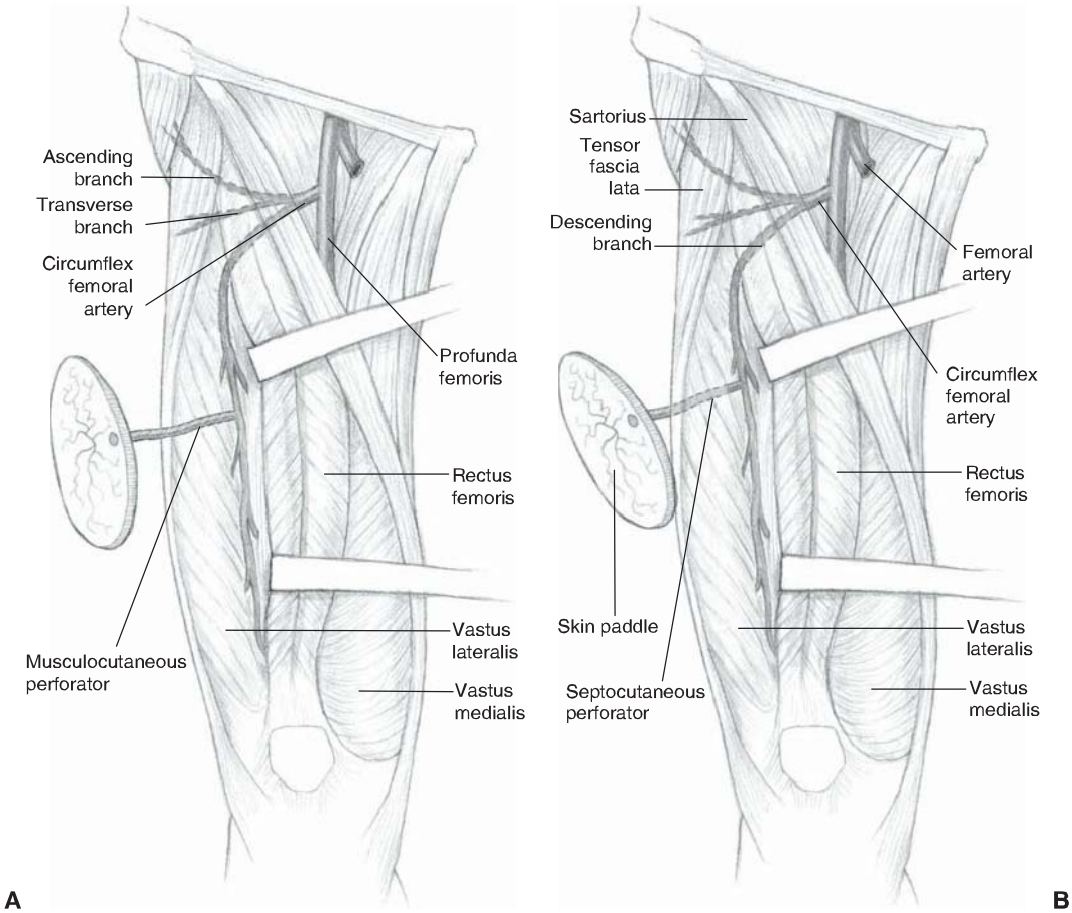

Figure 174.3 **A:** Type I vertical musculocutaneous perforator, which is the most common variant. **B:** Type III septocutaneous perforator.

long-term follow-up, morbidity will become better defined. Fortunately, most elevations are performed based on the perforator that spares the muscle and the nerve to the vastus lateralis, which is closely associated with vascular pedicle.

Technical Considerations

The location of the perforator is determined with a Doppler prior to elevation. Perforator-based elevation is accomplished by performing a suprafascial dissection until a perforator is located coursing through the fascia. Once located, the perforator is dissected proximally through the muscle or anterior to the muscle depending of the vascular variation that is encountered. The first incision is the medial incision over the rectus femoris. The paddle is elevated from medial to lateral until the perforator is identified. Once the perforator is identified, the dissection is carried along the perforator from lateral to medial. Multiple skin paddles and slips of muscle can be harvested based on the perforators that are present. Once the pedicle is defined, the lateral skin incision can be made to complete the elevation.

Preoperative Considerations

A history of vasculopathy with bypass grafts is a contraindication. For some reconstructions a larger muscle component may not be desirable. There is great variation of the thickness of the donor site between individuals, so skin paddle thickness needs to be assessed to be sure that it is appropriate for the recipient site.

Postoperative Management

The site can usually be closed primarily after the muscles have been approximated over a suction drain. Little rehabilitation is needed other than ambulation.

Temporoparietal

Description

In head and neck reconstruction, the fascia is most commonly transferred as a pedicled flap, but it also can be used as an autogenous transplant when the arc of rotation is inadequate. The donor site can be transferred independently or in combination with skin. The temporoparietal fascial skin can be harvested with dimensions of 17 × 14 cm with extensive scalp undermining. When skin is included, the thickness of the flap ranges from 2 to 4 mm. It is very uncommon to elevate this donor site with overlying skin except for reconstruction of the upper lip when hair is desired. As an autogenous fascial transplant, this donor site has highly specialized uses for hemilaryngeal reconstruction, or a low-volume cutaneous reconstruction when the forearm donor sites are not available. Most often it is used as a rotational flap in the midface, upper face, skull base, or lateral temporal bone to cover bone, support dural closure, or support calvarial bone grafts.

Neurovascular Pedicle

The temporoparietal scalp consists of five distinct layers (Fig. 174.4A). The temporoparietal fascia is deep to the skin and subcutaneous tissue, to which it is firmly bound. The temporoparietal fascia is superficial to the temporalis muscular fascia, which envelops the muscle. Above the superior temporal line, the temporoparietal fascia becomes the galea aponeurotica (24). The superficial temporal artery and vein, which supply this fascia and travel within the temporoparietal fascial layer, are best isolated approximately 3 cm superior to the root of the helix, where the vessels branch into frontal and parietal divisions. The flap is most commonly based on the parietal branch. The base is centered over the middle third of the superior auricular helix. The deep temporal artery arises from the proximal superficial temporal artery at the level of the zygomatic arch and supplies the temporalis muscular fascia. If the deep temporal artery is included, a two-paddled design can be raised on a single vascular pedicle (Fig. 174.4B).

Anatomic Variations

The superficial temporal artery consistently divides into two branches 3 cm above the root of the helix. Tracing the course of the posterior parietal branch with Doppler sonography helps center the fascial paddle and ensures that the planned territory of the temporoparietal fascial flap is well vascularized.

Potential Morbidity

The anterior dissection of the fascial paddle is limited by the course of the frontal branch of the facial nerve, which also is in the temporoparietal fascia. Secondary alopecia can be caused by injury to the hair follicles due to dissection that is too superficial. The venous pedicle can course with the artery or can course 2 to 3 cm posteriorly. Both the artery and vein must be included within the confines of the flap.

Technical Considerations

The superficial aspect of the fascia must be dissected first in a plane just below the hair follicles. The deep side of the donor-site elevation is a layer of loose areolar tissue that separates the temporoparietal fascia from the temporalis muscular fascia. The caudal extension of the pedicle dissection is limited by the location of the main trunk of the facial nerve.

Preoperative Considerations

Prior neck or parotid surgery, previous bicoronal incision, and external carotid embolization are relative contraindications to use of a temporoparietal fascial flap. Preoperative Doppler assessment of the patency and location of the pedicle is necessary.

Postoperative Management

The site can be primarily closed over suction drainage.

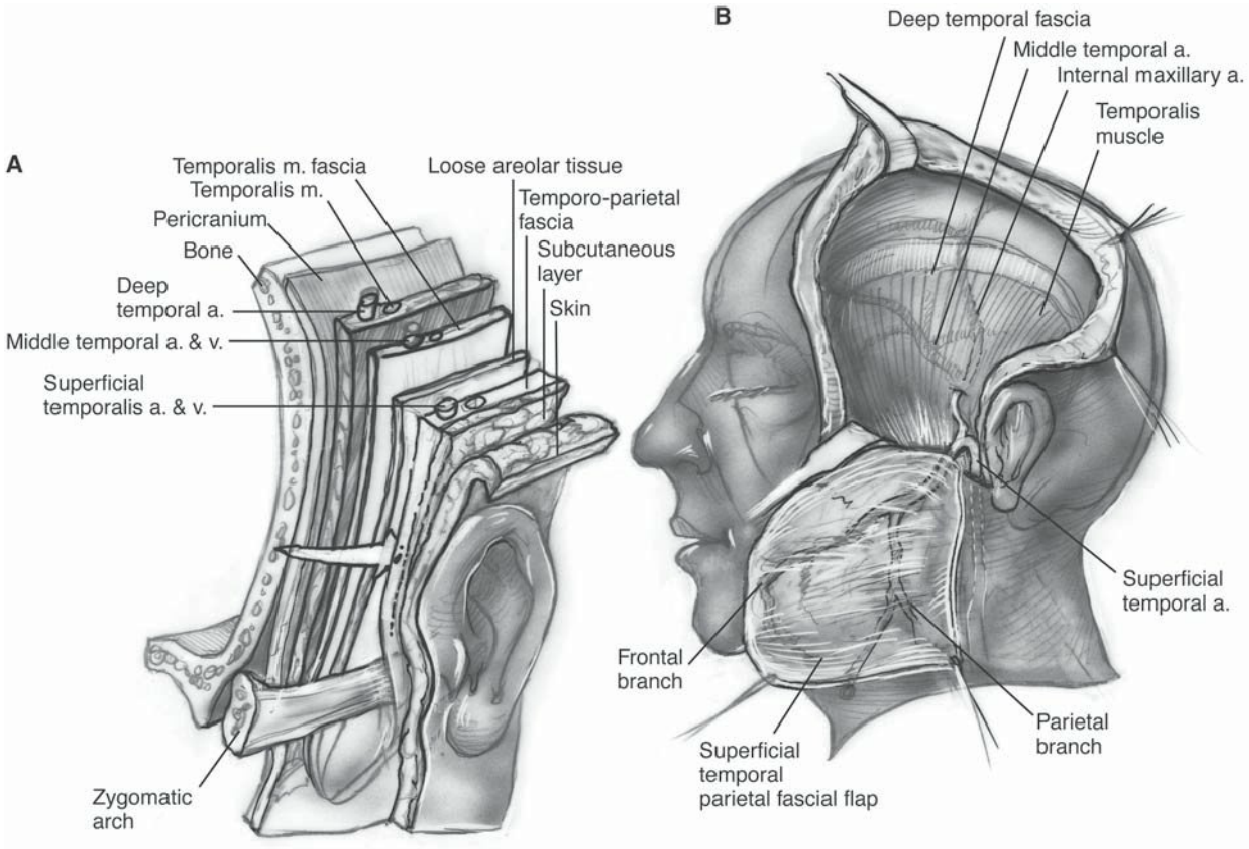

Figure 174.4 **A:** Cross section shows layers of the temporal scalp, superficial temporal space, and temporal skull. The superficial side of the temporoparietal facial flap is intimately associated with the subcutaneous fat of the scalp. The superficial dissection is started inferiorly just below the level of the hair follicles. As it proceeds superiorly, dissection becomes more difficult. *Arrow* denotes the deep side of the temporoparietal flap. **B:** Lateral view of the head with the temporoparietal flap folded inferiorly shows the vascular anatomic features. Dissection of the deep layer of the flap is in loose areolar tissue and is much more straightforward than is superficial dissection. Superficial dissection is completed before deep dissection.

MUSCLE AND MUSCULOCUTANEOUS AUTOGENOUS TRANSPLANTS

Rectus Abdominis

Description

The rectus abdominis donor site is relatively easy to harvest, has a long vascular pedicle, and is extremely reliable. The area of skin that can be harvested with a single rectus muscle encompasses a substantial portion of the abdomen and lower chest. Options for harvest can vary widely that include the entire muscle all the way to a cutaneous elevation that spares the muscle and is based on one to three perforators. This donor site was the most popular site for the reconstruction of most moderate- to high-volume head and neck defects. Its use is being replaced by the anterolateral thigh donor site except for the very large-volume defects or when the BMI of the patient is very low, and this is one of the remaining sites where there is ample subcutaneous fat. For many surgeons, this donor site is used to reconstruct high-volume defects such as total glossectomy defects, skull base defects, and large cutaneous defects. At present, this donor site is one of the best alternatives for total glossectomy defects, and for patients with favorable anatomy, the rectus fascia can be sutured to the mandible to maintain the tongue mound in a position to obliterate the oral cavity. The rectus fascia can also be used to suspend the larynx to the mandible. For patients with very low BMI and very little subcutaneous fat, the rectus abdominis donor site can be used to manage moderate-volume defects such as hemiglossectomy and lateral temporal defects. For hemiglossectomy defects where the management of the reconstructed volume is critical to long-term function, a perforator-based rectus elevation may be preferable. The exclusion of the muscle facilitates better control of the volume of the reconstructed defect because muscle, which eventually undergoes atrophy, is not included. The disadvantages of this donor site are poor color match to facial skin and the development of ptosis. The versatility of the rectus abdominis donor site is based on the pattern of vascular supply from the deep inferior epigastric system of vessels, as shown in Figure 174.5.

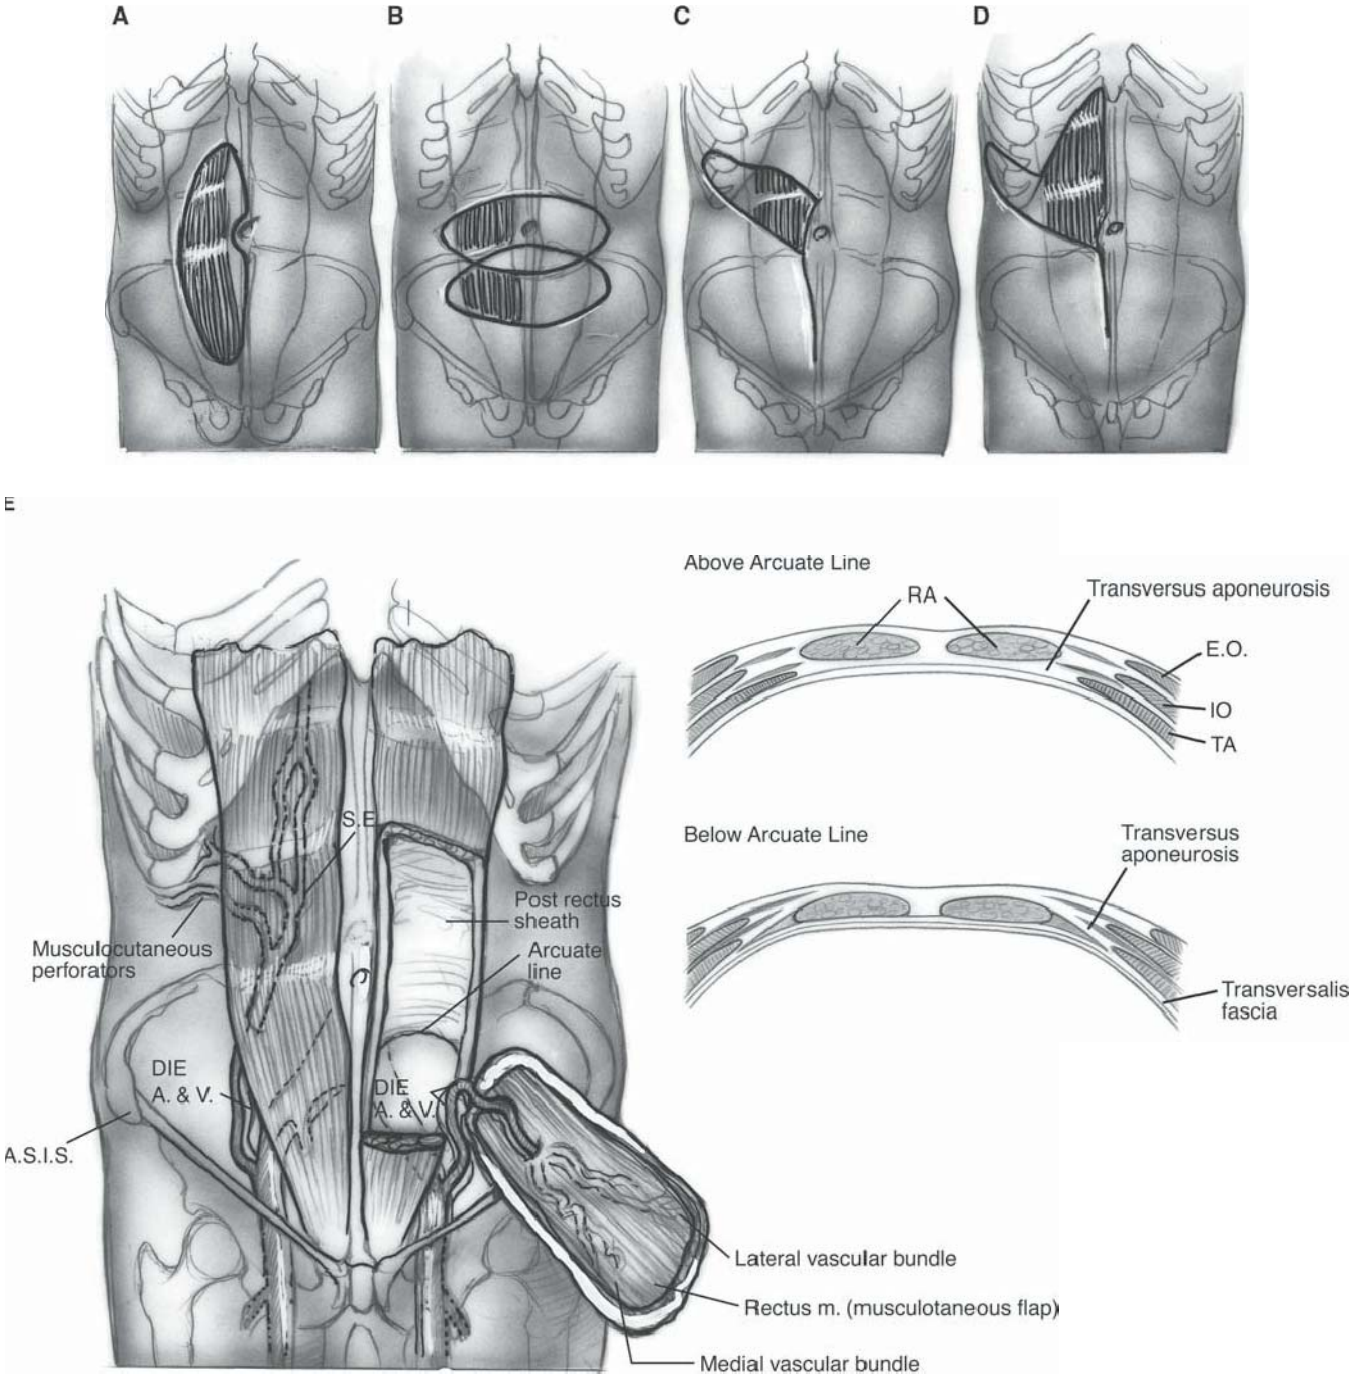

Figure 174.5 Versatility of the rectus abdominis flap. **A:** Vertical rectus flap. **B:** Middle and lower transverse rectus abdominis flaps. **C:** Thoracoumbilical rectus flap. **D:** Combined thoracoumbilical and vertical rectus flap. **E:** The abdominal wall with the left rectus muscle reflected inferiorly to expose the arcuate line. The layers of the rectus sheath are visible above and below the arcuate line. EO, external oblique; IO, internal oblique; RA, rectus abdominis; TA, transversus abdominis.

The most commonly used configuration of the rectus donor site is the transverse rectus abdominis myocutaneous (TRAM) for breast reconstruction. This configuration can be quite useful in the head and neck particularly when large volumes of tissue are required in low-BMI patients, when the entire rectus muscle is used and can act as a separate tissue paddle, or when cosmesis is an issue (e.g., a young, low-BMI patient with a large tongue defect).

Neurovascular Pedicle

The rectus abdominis muscle has two dominant vascular pedicles, the deep superior epigastric artery and vein and the deep inferior epigastric artery and vein (25). The deep inferior epigastric artery measures an average of 3 to 4 mm in diameter, and the musculocutaneous perforators are direct branches of the deep inferior epigastric artery that passes through the overlying rectus muscle to the overlying

skin. The autogenous transplant can be reinnervated with any of the lower six intercostal nerves that supply segmental motor and sensory innervation to the rectus abdominis muscle and sensory supply to the overlying skin. Unfortunately, because of the segmental innervation of this flap, it is difficult to perform effective motor or sensory reinnervation.

Anatomic Variations

Variations of the deep inferior epigastric artery and vein have been described. Sometimes the pedicle courses an unusually long distance along the lateral aspect of the muscle before taking a medial route. The perforator-based vascular anatomy is becoming more important because of the increasing use of perforator-based elevations (26).

Potential Morbidity

Removal of the rectus abdominis on one side with a portion of the overlying fascia can weaken the anterior abdominal wall and predispose the patient to ventral herniation or midline bulge. Primary closure with interrupted figure of eight with a 0.0 monofilament permanent suture on a taper needle may help decrease the likelihood of a hernia. The use of mesh to reinforce the abdominal wall is less frequent than in the past because of the high rate of infection. The time and effort needed to close the donor site and potential morbidity of the rectus donor site are other reasons that the anterolateral thigh donor site is replacing the rectus in all but the largest-volume defects.

Technical Considerations

Understanding the anatomic characteristics of the fascial envelope is perhaps more critical for rectus abdominis donor site than it is for any donor site (Fig. 174.5E). Prevention of herniation depends on restoring the integrity of the abdominal wall through effective closure of the fascial layers. An important transition occurs in the posterior sheath at the arcuate line, which is approximately at the level of the anterior superior iliac spine. Above the arcuate line, the posterior sheath is composed of contributions from the aponeuroses of the transversus abdominis and internal oblique muscles. Below the arcuate line, the aponeurotic extensions of all three muscle layers contribute to the anterior rectus sheath. The posterior sheath is composed only of transversalis fascia. The posterior rectus sheath is sufficient to prevent abdominal herniation or bulge above the arcuate line, although most surgeons reinforce this closure with closure of the anterior rectus sheath. Below the arcuate line, the anterior sheath must be reapproximated to prevent abdominal herniation. The donor site can nearly always be closed primarily. If the rectus fascia is not needed for the reconstruction, this donor site can be harvested as a perforator-based skin paddle. This technique spares the rectus muscle and the rectus sheath and avoids many of the potential morbidities of this donor site.

Preoperative Considerations

Preoperative assessment must include a careful history and physical examination of the abdomen to ensure that previous surgical procedures do not interfere with elevation of the donor site. This donor site has to be avoided in patients who have undergone inguinal herniorrhaphy or appendectomy because there can be scarring in the region of pedicle dissection. Peripheral vascular disease involving the iliac artery, particularly a history of vascular bypass, such as an aortofemoral bypass, is a contraindication to use of this donor site.

Postoperative Management

Ileus can occur in the early postoperative period. Vigorous exercise that involves the abdomen should be avoided for 3 months posttreatment although mobilization and exercise can be started before 3 months but should be done under supervision of rehab medicine or physical therapy.

Latissimus Dorsi

Description

A latissimus dorsi donor site can be used for head and neck reconstruction as either a pedicled rotation flap or an autogenous transplant. When the availability of a recipient vessel is in question, such as after radical neck dissection, this flap can be rotated onto the recipient site as a pedicled flap. When recipient vessels are available, the advantages of transferring the latissimus dorsi donor site as an autogenous transplant are as follows: there is more flexibility in positioning, the skin paddle can be inset more superiorly, and there is less risk of pedicle kinking. When the latissimus dorsi donor site is elevated as muscle alone, the muscle atrophies to a thickness of approximately 4 mm. This attribute makes it ideal for scalp reconstruction, but is poor for large-volume defects if the muscle is used to reconstitute the reconstructed volume. In the setting of massive scalp defects, which require the entire muscle, the elevation of the latissimus can be staged to recruit the distal, third angiosome. The staging procedure is performed by elevating the distal portion of the latissimus muscle and placing clips on 5 or 6 of the segmental, paravertebral, intercostal perforators from thoracic vertebrae 6 to 12 that supply the second and third angiosome. The latissimus muscle is definitively elevated 3 weeks later. For large-volume defects or large cutaneous neck defects, the latissimus dorsi muscle is transferred in a musculocutaneous paddle. For patients with total glossectomy defects, attempts have been made with little success to provide mobility of the tongue mound by reinnervating the latissimus dorsi muscle with the hypoglossal nerve.

Neurovascular Pedicle

The thoracodorsal vessels arise from the subscapular vessels or directly from the axillary artery and vein. These branches arise from the third portion of the axillary artery and vein and the vascular variations do not significantly affect pedicle length. The average diameter of the artery at

its origin is 2.7 mm (range, 1.5 to 4.0 mm), the diameter of the vein is 3.4 mm (range, 1.5 to 4.5 mm), and the average length of the pedicle is 9.3 cm (range, 6.0 to 16.5 cm). One of the many appealing features of this flap is the length of the vascular pedicle. The thoracodorsal nerve provides motor innervation to the latissimus dorsi muscle. The thoracodorsal nerve usually crosses the axillary vessels approximately proximal to the subscapular artery and vein.

Anatomic Variations

The arterial supply and venous drainage of the latissimus dorsi donor site has a number of anatomic variations, but none precludes elevation or compromises pedicle length. The anatomic variations involve independent origin of the thoracodorsal vein or the thoracodorsal artery from the axillary artery or vein. When the origins are separated, the subscapular artery arises proximally in the axilla by an average of 4.2 cm (27).

Potential Morbidity

Marginal necrosis of the skin paddle can occur but the most common cause is a skin paddle that is designed too distally over the third angiosome. There is little donor-site morbidity except when a pectoralis muscle flap has been elevated on the ipsilateral side.

Technical Considerations

The patient must be carefully positioned on a beanbag in a semidecubitus position. With the patient in a 15-degree semidecubitus position, the donor site can be harvested simultaneously with the resection of the primary lesion. The anterior border of the latissimus dorsi muscle is along a line between the midpoint of the axilla and a point midway between the anterior superior iliac spine and the posterior superior iliac spine. The thoracodorsal artery and vein enter the undersurface of the muscle 8 to 10 cm below the midpoint of the axilla. The vascular branches to the serratus anterior muscle are ligated during elevation. The surgeon can harvest either a limited amount of latissimus dorsi muscle under the skin or the entire muscle, depending on reconstructive demands. A two-paddle design can be based on the medial and/or the lateral branches of the thoracodorsal vessels (Fig. 174.6). A useful elevation technique is a muscle-sparing approach that is based on the lateral branch of the thoracodorsal artery and includes only the lateral edge of the latissimus. The advantages are

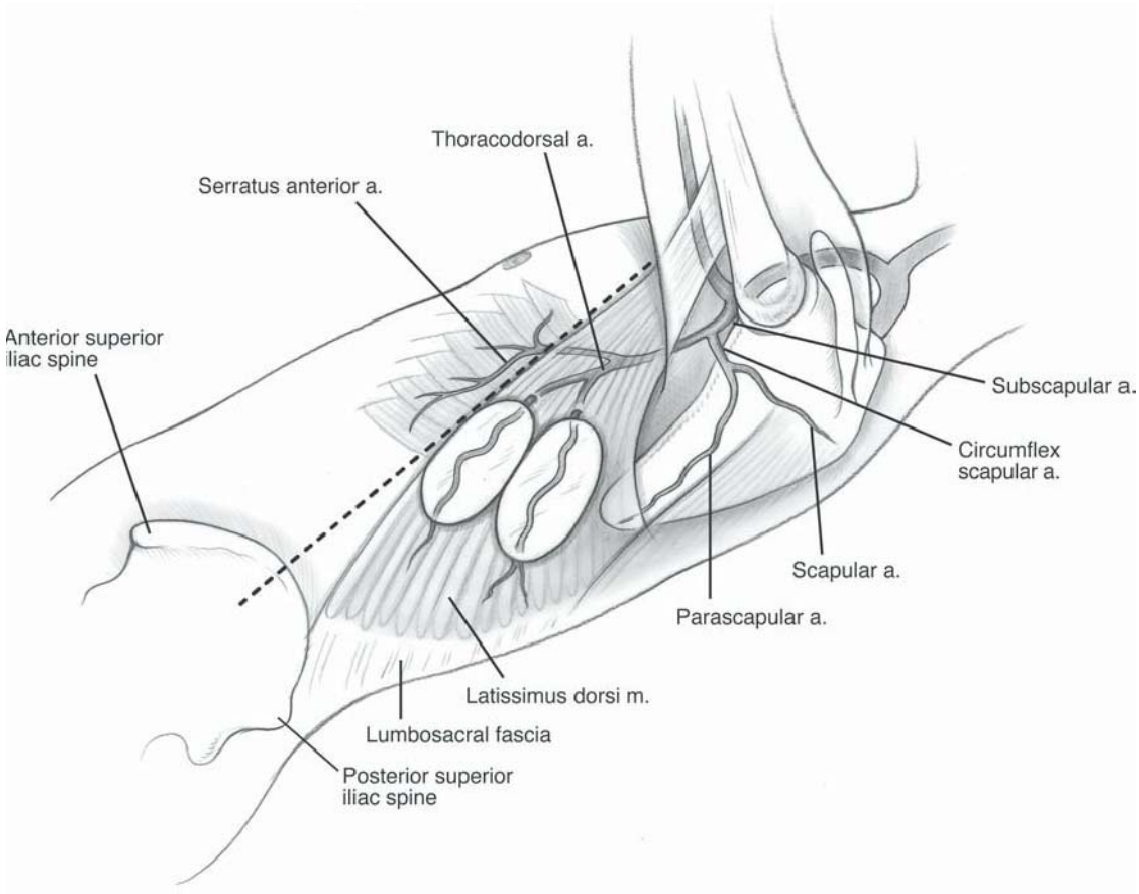

Figure 174.6 Left flank with the patient in the lateral decubitus position. The medial and lateral branches of the thoracodorsal artery are visible at the anterior edge of the muscle. The distal muscle can be used if a delay procedure that involves dividing the paraspinous perforators is performed 2 to 3 weeks before harvest. Additional pedicle length can be obtained if the circumflex scapular artery is divided.

harvest of a small volume of latissimus muscle, preservation of the innervation of the latissimus muscle from the medial branch of the thoracodorsal nerve, better control of the reconstructed volume because there is less muscle that will undergo atrophy, and less deficit in shoulder function because of preservation of innervated muscle at the donor site.

Preoperative Considerations

Previous axillary lymph node dissection is a relative contraindication to the use of the latissimus dorsi donor site. History of shoulder injury particularly of the rotator cuff is a relative contraindication.

Postoperative Management

Suction drains must be placed and left in place for several days postoperatively because of the high incidence of seroma that occurs with use of with the latissimus dorsi donor site.

Gracilis

Description

This thin myocutaneous donor site from the medial thigh was introduced by Harii et al. (28), in 1976, and was subsequently popularized as a muscle-only design for dynamic facial reanimation. The primary use of the gracilis muscle in the head and neck has been facial reanimation, in which the muscle is both revascularized and reinnervated to restore contractile activity. To restore synchronous mimetic movement when the proximal stump of the facial nerve is not available, a two-stage procedure is performed with a cross-face sural nerve graft at the initial stage. The Tinel sign is used to monitor the progression of axonal growth across the face, which usually takes 9 to 12 months after initial transfer. When the examination shows that the distal end of the sural graft has viable axons, the free muscle is transferred, revascularized, and reinnervated to the stump of the cross-face nerve graft. The advantages of this donor site for facial reanimation are its neuromuscular structure and ease of dissection.

Neurovascular Pedicle

The dominant pedicle of the gracilis donor site is the terminal branch of the adductor artery, which arises from the profunda femoris artery and runs a circuitous course between the adductor longus muscle anteriorly and the adductor brevis and magnus muscles posteriorly before entering the gracilis at the junction of the upper third and lower two-thirds. The point of entrance of the vascular pedicle into the muscle is consistently between 8 and 10 cm inferior to the pubic tubercle. The artery to the gracilis is accompanied by two venae comitantes, which either join or drain separately into the profunda femoris vein. The caliber of the artery usually is 2 mm, and the caliber of the venae comitantes measures 1.5 to 2.5 mm. The motor supply to the gracilis muscle is the anterior branch of the obturator nerve, which enters the muscle in an oblique course approximately 2 to 3 cm cephalic to the entry point of the vascular pedicle (27).

Anatomic Variations

The main variability of the gracilis donor site is the blood supply to the overlying skin rather than the vascular or nerve supply to the muscle. Yousif et al. (29) described variations in which there are no musculocutaneous perforators from the gracilis muscle, and most of the skin supply was from septocutaneous vessels or from the inferior branch of the superior external pudendal artery. This variation is rarely important because this donor site is used as a muscle-only donor site for facial reanimation.

Technical Considerations

The branching pattern of the anterior division of the obturator nerve allows separation of the gracilis muscle into at least two functional muscular units. To minimize the bulk of muscle transferred, a single neuromuscular unit can be transferred that innervates the anterior portion of the muscle. The skin paddle, when needed, can be oriented longitudinally over the gracilis muscle. The cutaneous paddle must be centered over the dominant musculocutaneous perforator, which is 8 to 10 cm distal to the pubic tubercle (Fig. 174.7).

COMPOSITE-FREE DONOR SITES

Fibular Osteocutaneous

Description

The free fibular graft was first described by Taylor et al. in 1975 (30) for long-bone replacement after trauma or cancer. Hidalgo (31) first described the free fibular donor site for mandibular reconstruction in 1989. The fibula provides the longest possible segment of revascularized bone (25 cm) and has the thinnest associated skin paddle. This osseous donor site is the only donor site that many reconstructive surgeons use for bony reconstruction of the head and neck. The other two osseous donor sites are the iliac crest and the scapula. The iliac crest is less favored by some surgeons because of the donor-site morbidity and more difficult closure despite the excellent quality of the bone. The scapular donor site is less favored by some surgeons because the location of the scapular bone makes two-team surgery more difficult, the scapular bone is shorter, and the cross-sectional bone density is less than the fibula despite the superior selection of soft tissue options.

Due to the small volume of the fibula skin paddle, large-volume soft tissue defects may require a second revascularized flap. Although the fibula can span nearly any mandibular defect, it lacks the diameter to reconstruct many dentulous mandibles. Unless adjunctive procedures are performed such as onlay bone grafting or vertical distraction osteogenesis, it lacks the cross-sectional diameter

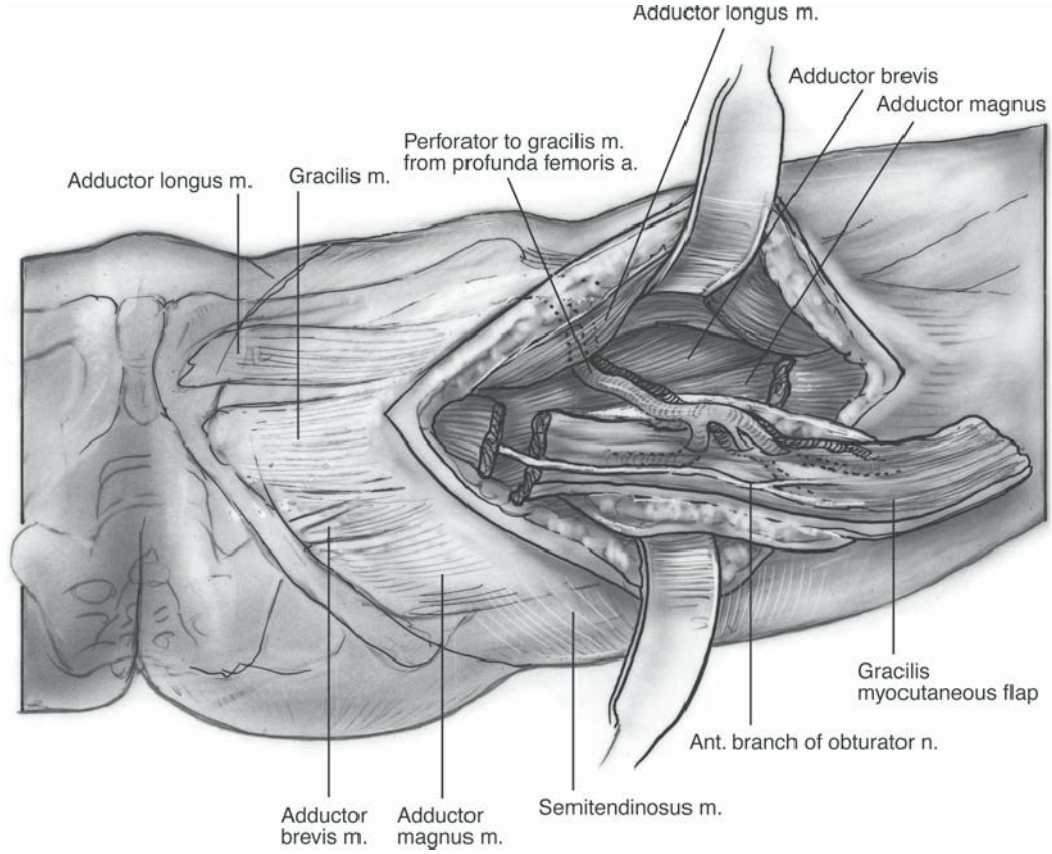

Figure 174.7 The inner thigh of the left leg with a musculocutaneous gracilis flap dissected and only attached by its pedicle. The patient is positioned with the knee flexed and the hip externally rotated. With the knee flexed, the anterior edge of the gracilis muscle is marked with a line from the adductor tubercle to the tibial tubercle. The pedicle inserts on this line approximately 8 to 10 cm from the adductor tubercle.

to reliably fix osseointegrated implants for implant bone prosthesis. The fibula is also useful for infrastructure (oral palate) maxillary reconstruction because of its long pedicle, thin associated skin paddle, and small-caliber bone stock (32). If more than 60% of the maxillary alveolus is reconstructed, vein grafting may be required. The fibula is not ideal for the reconstruction of larger maxillary defects that include the infraorbital rim because of the relative lack of soft tissue and the complex osteotomies required to reconstruct the infraorbital rim and the alveolus simultaneously. This donor site is ideal to a two-team approach and is one of the reasons for its popularity.

Neurovascular Pedicle

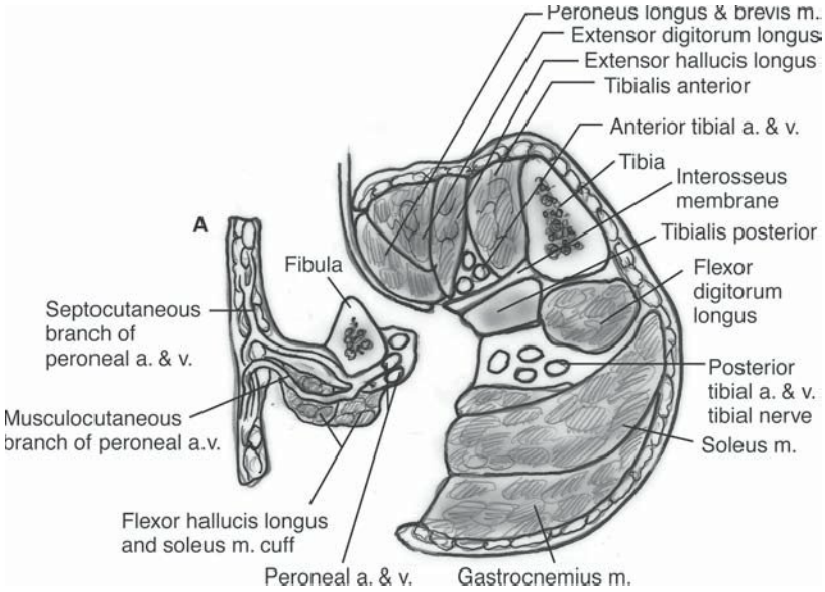
The peroneal artery and vein provide the primary blood supply to the fibular osteocutaneous donor site. Preoperative angiography or magnetic resonance angiography is recommended to ensure adequate arterial supply to the foot when the peroneal artery is sacrificed (33). Sensation can be variably restored when the lateral sural cutaneous nerve is used. The branches, once they supply the skin paddle, can be multiple, small, and tedious to dissect. The peroneal communicating branch can be harvested as a vascularized nerve graft but is rarely performed in clinical practice.

Anatomic Variations

Much has been reported on the reliability of the blood supply to the skin (34). The perforators that supply the skin can course through the posterior intermuscular septum as septocutaneous perforators or can travel as musculocutaneous perforators through the flexor hallucis longus and soleus muscles. A cuff of flexor hallucis longus and soleus should be included during the elevation (Fig. 174.8A). The skin paddle is reliable if it is designed around a perforator.

Technical Considerations

When preoperative evaluation shows that either fibula is a suitable donor site, the donor site is chosen on the basis of ease of insetting. If the skin paddle is to be placed intraorally, the autogenous transplant should be harvested from the contralateral leg to the side of the inset and vascular anastomosis. If the skin paddle is to be placed extraorally, the elevation should be ipsilateral to the side of inset and vascular anastomosis. The skin paddle is centered over the posterior intermuscular septum, which is anterior to



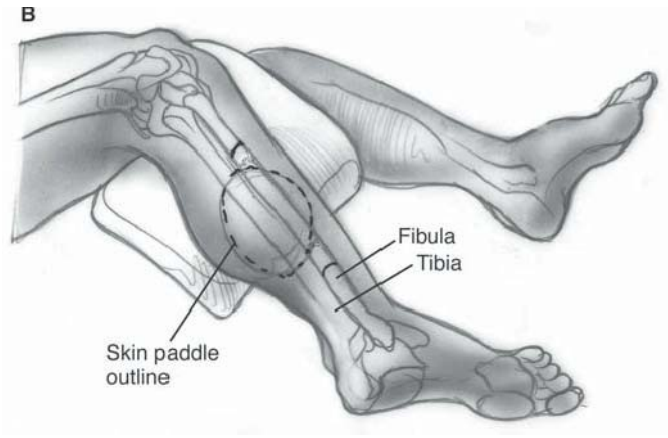


Figure 174.8 **A:** Cross section of the leg shows the fibula flap is elevated, and that both musculocutaneous and septocutaneous perforators course from the peroneal artery to the skin paddle. **B:** The flap is marked on the lateral aspect of the right leg. The cutaneous paddle is marked along the posterior intermuscular septum, which is visible when the foot is flexed and inverted. Dominant cutaneous perforators can be located with a Doppler flowmeter before the flap is elevated (10 to 25 cm distal to the fibular head). The presence of septocutaneous perforators can be confirmed after the cutaneous portion of the flap over the lateral compartment is elevated. **C:** Flap detached from the vascular pedicle with the soleus muscle still attached for illustrative purposes. The anterior approach to this flap is useful for obtaining a wide cuff of flexor hallucis and soleus muscles to encompass the musculocutaneous perforators.

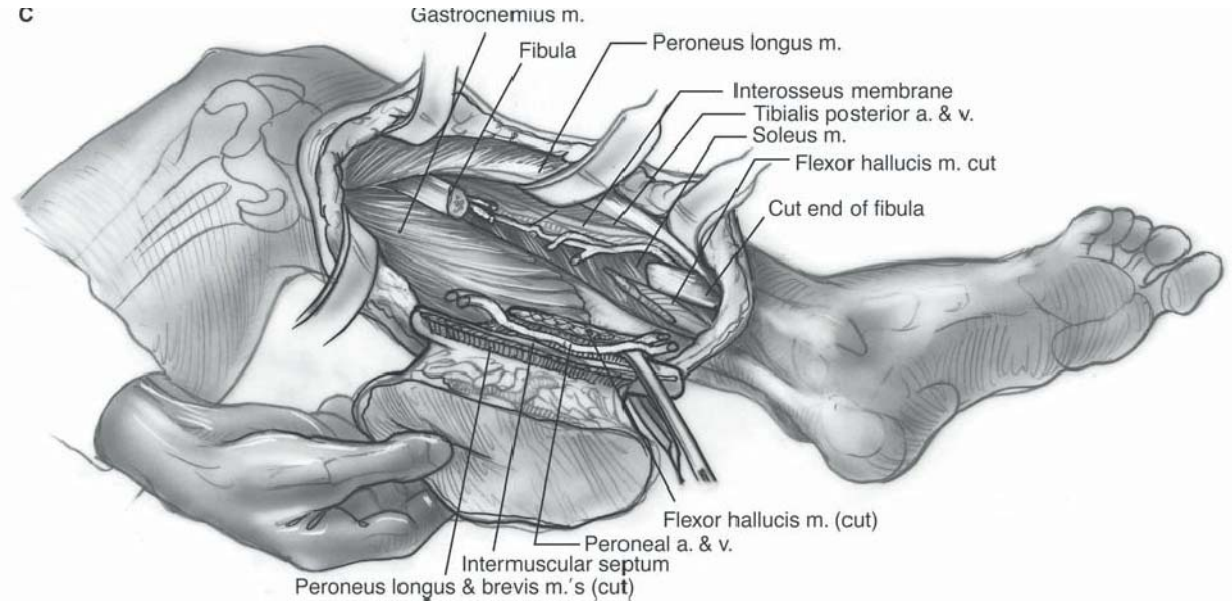

the soleus muscle and posterior to the peroneus muscle (Fig. 174.8B and C). A Doppler is used to identify cutaneous perforators along the posterior septum along the distal third of the donor fibula bone. The greatest number of cutaneous perforators is present in this region. Shifting the skin paddle distally increases pedicle length. Elevation usually is performed with a thigh tourniquet inflated to 300 mm Hg. In the event that the skin paddle is inadequately perfused, a second soft tissue donor site is prepared, which is usually the radial forearm site.

Potential Morbidity

A variety of donor-site complications have been reported, including rolling out of the ankle, cold intolerance, and edema. Elevation and closure are important. The motor nerve to the lateral compartment will be exposed when the peroneal muscles are dissected from their origin on the fibula. It is not technically challenging to avoid this nerve, but knowledge of its location will facilitate identification and preservation. When reapproximating the muscles after elevation of the fibula, it is important to not injure the nerve supply to the lateral compartment and to reapproximate the flexor hallucis at an anatomic length so that it can effectively flex the toe. An 8-cm segment of fibula is preserved both proximally and distally to protect the common peroneal nerve proximally and to ensure stability of the ankle joint distally. A skin graft is often required for closure of the donor defect and is preferable to closure under excessive tension because of the risk of compartment syndrome or distal limb ischemia.

Preoperative Considerations

Assessment of the vasculature to the foot is essential before fibular transfer. MRI angiography has supplanted conventional angiography in most cases. A history of lower-extremity fracture, joint replacement, and bypass grafting directs the surgeon away from a particular extremity. Careful physical examination of the lower extremity for peripheral edema or nonhealing ulcers is advisable in selection of the donor site because diseases related to peripheral vascular compromise and peripheral neuropathy such as diabetes may direct the surgeon to alternative donor sites.

Postoperative Management

Distal pulses in the foot are monitored as closely to avoid the complication of vascular insufficiency to the foot, which can be caused by excessively tight closure or dressings. A prefabricated walking boot is fit in the operating room. It is left in position for 6 to 7 days to facilitate healing of the skin graft. After this time period, the dressing is changed daily, the patient wears the boot for another 3 to 5 weeks to allow complete healing of the skin graft and to control pain. Ambulation is initiated with partial weight bearing on the third postoperative day with the assistance of physical therapy and a walker. Full weight bearing with the assistance of a walker or a cane can take place on postoperative day 5.

Osteocutaneous and Osteomusculocutaneous Iliac Crest

Description

The iliac crest donor site can be designed as an osseous, myoosseous, or osseomyocutaneous flap. The pedicle is 5 to 6 cm long and can be lengthened if the segment of iliac crest is harvested at a more distal site. The original descriptions of the donor site (30,35) were for mandibular reconstruction. Up to 16 cm of bone can be harvested. A bone-only transplant is ideal for segmental mandibular defects with very limited soft tissue component such as those associated with odontogenic lesions. A myoosseous transplant is ideal for segmental mandibular and maxillary defects with limited associated soft tissue defects. The osseomyocutaneous transplant is excellent for defects that involve limited intraoral lining and large external skin defects. The skin paddle does not rotate easily into the oral cavity and is not particularly useful for intraoral reconstruction. If there is a large intraoral soft tissue component combined with a segmental mandibular defect, the scapula donor site or two separate donor sites may be a better alternative. The iliac crest is also the best flap for retention of osseointegrated implants as it has the largest cross-sectional area when compared to a fibular or scapular bone. Despite the excellent quality of the bone, the limitations of the soft tissue and the morbidity at the donor site limit the use of the iliac crest. Most oral cavity defects usually involve intraoral soft tissue of the tongue, cheek, or palate and would require a second flap to adequately reconstruct the soft tissue. In cases where excellent bone stock is required for osseointegrated implants and there is a complex intraoral soft tissue defect, a second soft tissue donor site will be required to adequately rehabilitate the patient.

Neurovascular Pedicle

The deep circumflex iliac artery (DCIA) arises from the lateral aspect of the external iliac artery approximately 1 to 2 cm cephalic to the inguinal ligament. The ascending branch of the DCIA supplies the internal oblique muscle in 80% of the cases. The remaining patients have multiple smaller branches supplying the internal oblique from the DCIA. This vascular pattern does not prevent use of the internal oblique muscle. The deep circumflex iliac vein usually is composed of two paired venae comitantes, which merge a variable distance lateral to the external iliac vein. The caliber of the DCIA is 2 to 3 mm. That of the deep circumflex iliac vein ranges from 3 to 5 mm. There is no easily identifiable sensory component.

Potential Morbidity

Herniation of the abdominal wall can occur in the postoperative period. Meticulous, layered closure of the abdominal wall is essential to prevent ventral hernia. The transversus abdominis muscle is approximated to the cut

edge of the iliacus muscle. This layer can be reinforced by means of placing drill holes into the cut edge of the iliac bone through which sutures are placed to reinforce the deep layer of closure. The next layer of closure approximates the external oblique muscle and aponeurosis to the tensor fascia lata and gluteus medius muscles. To decrease the likelihood of direct herniation, the internal oblique muscle is retained in a position inferior to the anterior superior iliac spine. This triangle of muscle is closed back to the lateral rectus sheath, 2.0 or 0.0 Prolene is used, and a figure-of-eight suture is placed for each layer of this closure. The iliac crest donor site has robust blood supply to the bone and internal oblique muscle, but problems can occur with the blood supply to the skin. The skin is supplied by perforators from the DCIA. The perforators can be easily sheared as they pass through all three layers of the abdominal wall.

Technical Considerations

The skin paddle is centered on an axis drawn from the anterior superior iliac spine to a location on the anterior thorax where the inferior tip of the scapula is projected from the back to the anterior thorax (Fig. 174.9). Along this line, the zone of cutaneous perforators starts approximately 9 cm from the anterior superior iliac spine. The perforators are about 2.5 cm medial to the edge of the iliac crest. A generous cuff of external oblique, internal oblique, and transversus abdominis layers must be preserved as the cutaneous perforators course through these layers. This produces a bulky, relatively immobile skin paddle. The skin must not be rotated independently of the bone to avoid twisting or stretching the cutaneous perforators. This elevation also places that patient at greater risk for an incisional hernia.

Preoperative Considerations

Evidence of ventral herniation or previous inguinal herniorrhaphy can lead the surgeon to select an alternative donor site. If the patient has severe peripheral vascular disease, the surgeon needs to be sure that iliac artery bypass grafting has not been performed. For a patient who is a vasculopath and has not undergone bypass grafting, an angiography of the DCIA is performed to ensure vessel patency.

Postoperative Management

Progressive mobilization begins on the third postoperative day. On the fifth postoperative day, the patient can walk with a walker and progress to a cane and independent walking as tolerated. Rigorous abdominal exercise is avoided for 3 months after the completion of treatment including chemoradiation.

Scapular Donor Site, Subscapular and Thoracodorsal Artery

Description

The use of the scapular donor site is evolving and is different from the other commonly used osseous donor sites. The scapula bone and associated soft tissue can be harvested based on two different vascular pedicles, the circumflex scapular artery and/or the thoracodorsal artery. The unique features that make the scapular donor site useful for head and neck reconstruction include an option for a long vascular pedicle, the abundant surface area of relatively thin skin, the independent arc of rotation of the bone and the soft tissue paddles, the ability to combine the scapular flap based on the circumflex scapular artery with the latissimus dorsi based on the thoracodorsal artery, and the options

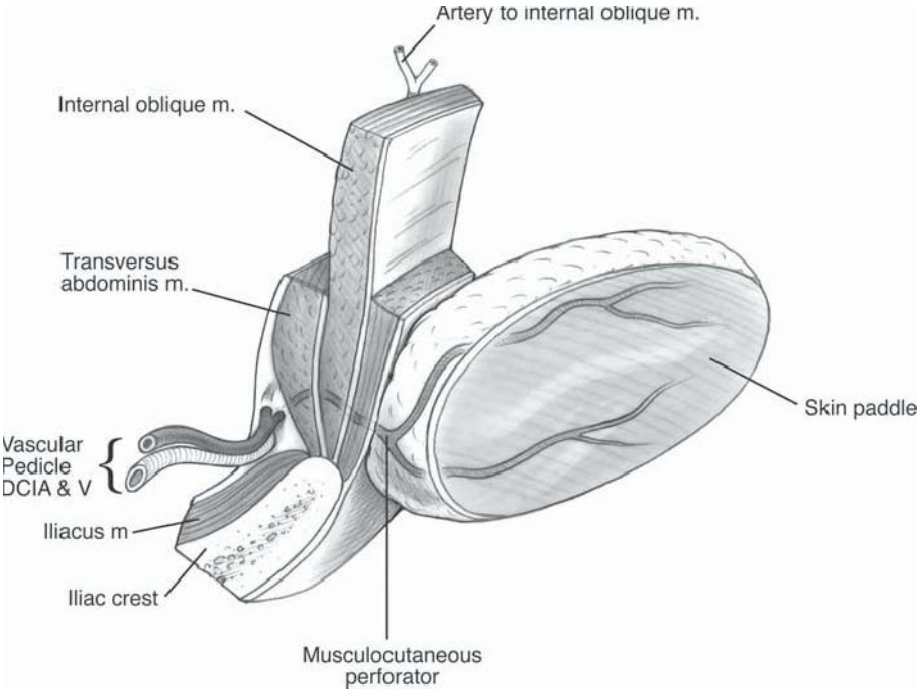

Figure 174.9 Vascular anatomic features of the iliac crest flap. The deep circumflex iliac artery (*DCIA*) courses in the superior aspect of the iliacus muscle. After it gives off the ascending branch, the DCIA runs in the groove between the iliacus and transversus abdominis muscles before penetrating the transversus abdominis muscle and passing over the pelvic brim near the posterior superior iliac spine. The bone must be cut low enough to include the pedicle. The ascending branch can be identified on the undersurface of the internal oblique muscle and dissected proximally to help identify the DCIA. *DCIV,* deep circumflex iliac vein.

for sophisticated three-dimensional inset. The flexibility of this donor site is useful for the closure of complex multisurfaced defects such as craniofacial and orofacial defects. Up to 10 cm of bone can be harvested from the lateral aspect of the scapula starting just inferior to the glenoid fossa based on the circumflex scapular artery. The bone stock is inadequate for the placement of osseointegrated implants for the purpose of mandibular rehabilitation without secondary onlay-free bone grafting. The fasciocutaneous skin paddle supplied by the circumflex scapular artery is an excellent source of well-vascularized, moderately thin, hairless skin. The circumflex scapular artery has two cutaneous branches that can supply two cutaneous skin paddles. The horizontally oriented scapular skin paddle is based on the transverse cutaneous branch, and the vertically oriented parascapular skin paddle is based on the descending cutaneous branch (36) (Fig. 174.10). The second vascular pedicle that supplies the tip of the scapula is the thoracodorsal, and this variation is being used with increasing frequency and is replacing the circumflex scapular-based donor site (37). The scapular tip is supplied by several branches from the thoracodorsal artery and is named the TDAST donor site (38). This variation has a long vascular pedicle, supplies the entire scapular tip, and is useful for complex multisurfaced, high-volume midface and combined orbital reconstructions. This variation can be considered a latissimus osseomyocutaneous flap and can be combined with any variation of the bone and/or soft tissue based on the circumflex scapular artery.

Neurovascular Pedicle

The parent vessels of the two scapular donor sites are the subscapular artery and vein, which arise from the third part of the axillary artery and vein. The circumflex scapular

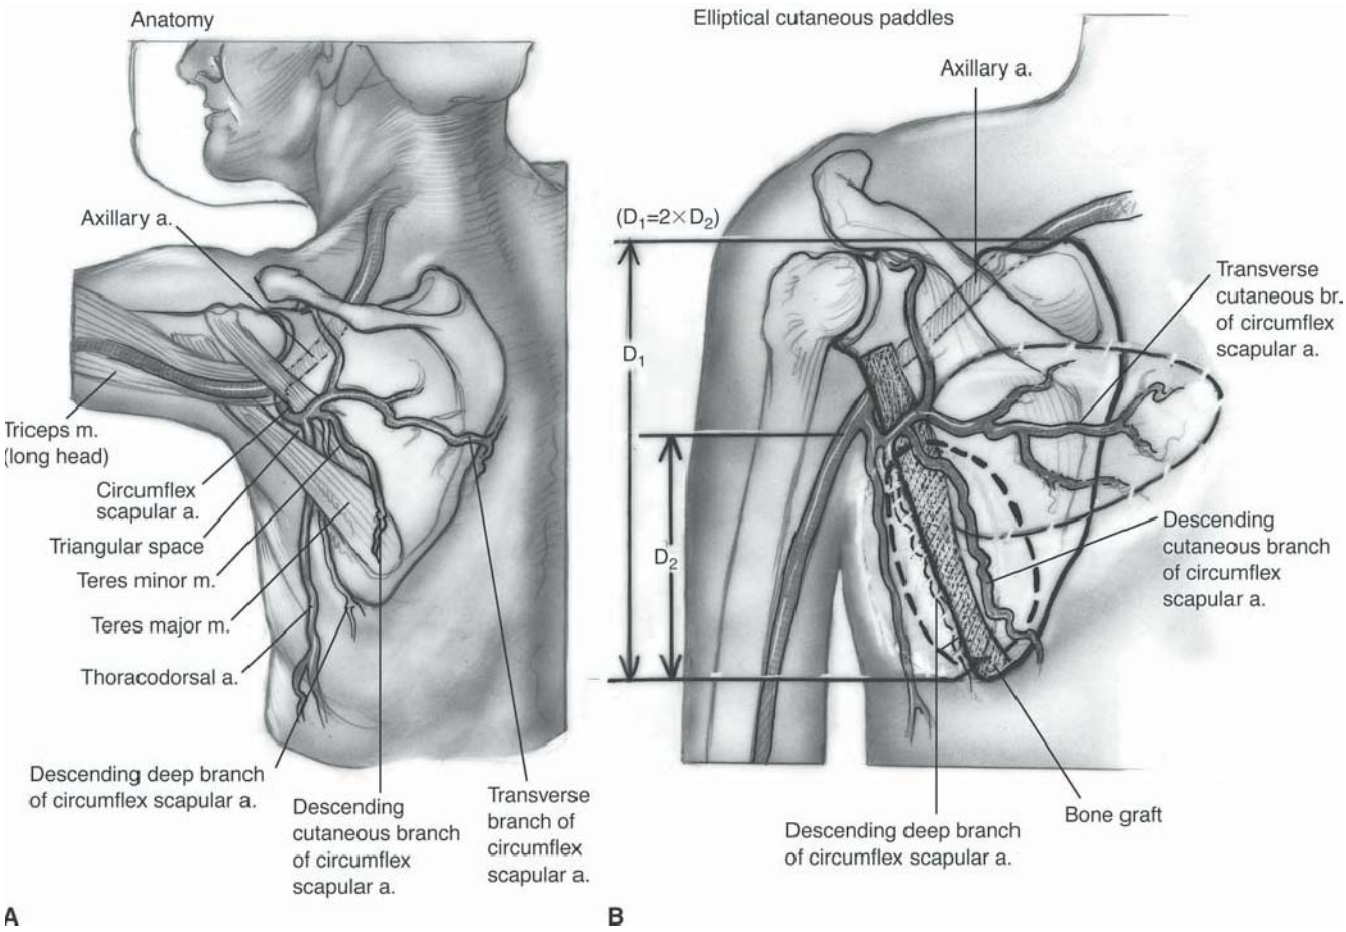

Figure 174.10 **A:** Vascular anatomic features of the left scapula. The subscapular artery sends the circumflex scapular branch through the triangular space to the scapular flap. The muscles that define the triangular space are palpated and marked preoperatively. The soft triangle is best approached by means of dissection over the teres major muscle at the lateral boarder of the scapula. Once the triangular space is located, the teres minor muscle can be retracted superiorly, and the pedicle can be dissected through the axillary space. **B:** The triangular space also can be located by means of marking the midpoint of the lateral aspect of the scapula. Three of the possible scapular paddles and their vascular supply are outlined. The deep branch is intimately associated with the lateral border of the scapula, which it supplies. If a bone flap is to be included, care is taken not to injure the deep branch after dissection of the cutaneous flaps.

artery and vein emerge from the triangular space defined by the teres major and teres minor muscles and the long head of the triceps muscle. The circumflex scapular artery is accompanied by paired venae comitantes, which usually join the thoracodorsal vein before entering the axillary vein. The average diameter of the circumflex scapular artery at its takeoff from the subscapular artery is 4 mm. At its origin from the axillary artery, the subscapular artery has an average diameter of 6 mm. When the circumflex scapular artery is harvested at its takeoff from the subscapular vessels, the fasciocutaneous flap has a pedicle length of 4 to 6 cm. Although a maximum pedicle length of 11 to 14 cm has been extensively quoted in the literature, in practice, the length is much closer to 8 cm. The thoracodorsal artery is described in the section on the latissimus dorsi myocutaneous donor site. The pedicle that supplies the scapular tip arises within 1 cm of the branch to the serratus muscle and can arise from the thoracodorsal artery or the artery to the serratus muscle (Fig 174.11). When skin or osseous paddles are elevated on both the circumflex scapular and the thoracodorsal pedicles, this configuration is referred to as a "mega" flap.

Anatomic Variations

There are five anatomic variations but they are of little clinical consequence from the perspective of pedicle length or viability of the transplant. The most common pattern is a single subscapular artery and a single subscapular vein branching into the circumflex scapular and the thoracodorsal pedicle supplying both the scapula and the latissimus donor sites. One of the variations is a duplicated circumflex artery. Of the remaining three variations, all are related to separate origins of the vein or artery for each of the two flaps. These variations may necessitate two recipient arteries or two recipient venous anastomoses.

Potential Morbidity

A contralateral brachial plexus neuropathy can be caused by lateral decubitus positioning during flap harvest. If the patient is positioned fully decubitus, an axillary roll is needed, as is careful attention to arm positioning. The axillary roll is to keep the thoracic cage elevated up off the bed and prevent compression of the clavicle on the brachial plexus. The scapular osteotomy must be fashioned 1 cm inferior to the glenoid fossa to avoid injury to the joint space. Harvest of the scapular osteocutaneous flap necessitates detachment of the teres major, teres minor, subscapularis, and infraspinatus, which can cause shoulder weakness and limited range of motion. These muscles must be meticulously reapproximated while the shoulder is abducted and the arm is extended.

Technical Considerations

To make two-team surgery easier, the patient can be placed in a 15-degree decubitus position with the assistance of a beanbag. Flap harvesting is technically more difficult when the patient is in a 15-degree decubitus position, but the benefit is reduction in total operative time. A separate

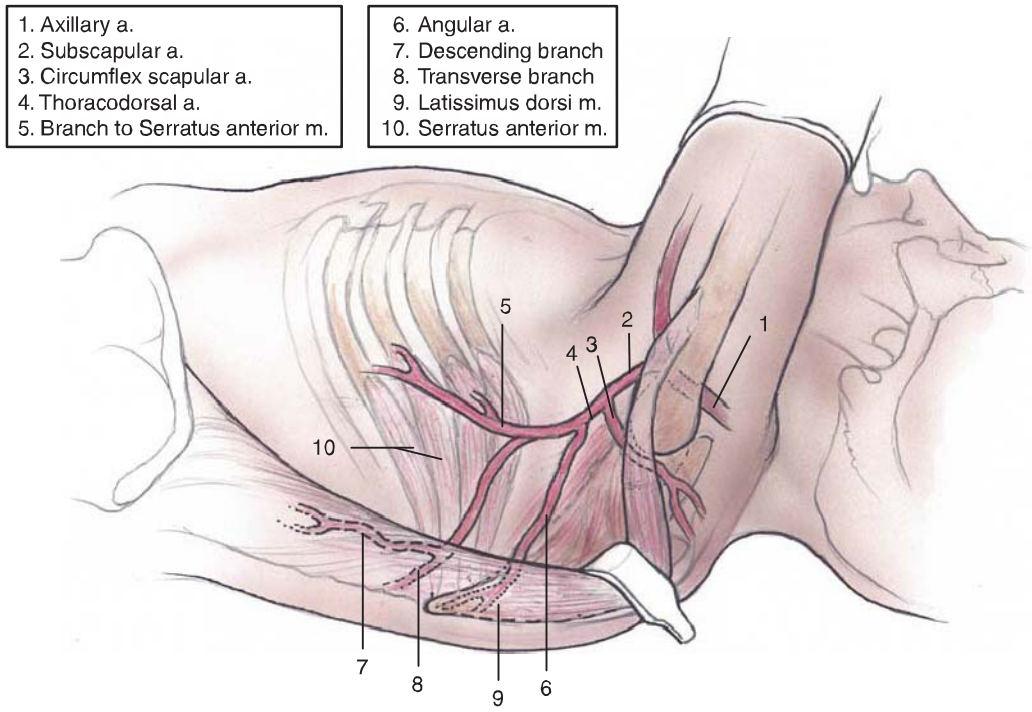

Figure 174.11 The vascular anatomy of the TDAST autogenous transplant as seen during surgical elevation with the patient in the semidecubitus position. Note that the branch to the scapular tip usually arises 1 cm distal to the serratus branch or from the serratus branch 1 cm after the serratus branch is given off from the thoracodorsal artery.

axillary incision can be helpful in dissecting the pedicle to the axillary artery and vein. If the bone of the scapula is elevated, the teres major, subscapularis, and latissimus dorsi muscles are reattached to the scapula with 2-0 PDS. Care is taken not to injure the motor nerve supply to the teres major muscle during flap elevation. Modified Kessler suture technique can be useful for optimizing reapproximation of the cut end of the teres major muscle to the scapula. If the scapular tip is harvested as part of a TDAST elevation, the insertion of the serratus should be reapproximated to stabilize the scapula. If there is enough intact latissimus muscle that is attached at the origin and the insertion, the anterior edge should be tacked to the fascia over the thoracic cage.

Preoperative Considerations

Previous axillary node dissection, shoulder reconstruction, or shoulder dislocation are contraindications to the use of fasciocutaneous and osteofasciocutaneous scapular or TDAST transplants.

Postoperative Management

If the scapular skin paddle is raised without bone, no specific limitations are necessary with active range of motion. Passive range of motion should be limited by pain. If bone is harvested, the shoulder does not have to be immobilized, but minimal mobilization and not using the axilla to move the patient in bed should continue for 5 days. Thereafter, a physical therapy program should be started that begins with active range of motion and progresses to passive range of motion.

VISCERAL DONOR SITES

Jejunum

Description

The free jejunal autogenous transplant has been successful in reconstruction of circumferential pharyngoesophageal defects. The diameter of the jejunum is a good match with the cervical esophagus and maintains a mucosal surface for food bolus transit. The graft is harvested by a transplant thoracic surgeon or a general surgeon with a simultaneous two-team approach.

Neurovascular Pedicle

Transilluminating the mesentery facilitates selection of a segment of jejunum with sufficient arborization from a single mesenteric artery and vein to supply the graft (Fig. 174.12). The second arcade of the jejunum usually is best for pharyngeal reconstruction.

Potential Morbidity

Stricture of the upper or lower anastomosis occurs in about 10% of free jejunal transfers and responds well to dilation. This rate of stricture is lower than that encountered when tubed cutaneous flaps are used. Despite the lower stricture rate and relative ease of inset, the jejunum can have long-term functional problems. The peristalsis of the jejunum produces functional obstruction during swallowing, a wet voice among patients who speak by means of tracheoesophageal puncture, and dysgeusia from the succus entericus (39). The long-term functional problems can be nearly eliminated with postoperative radiation therapy.

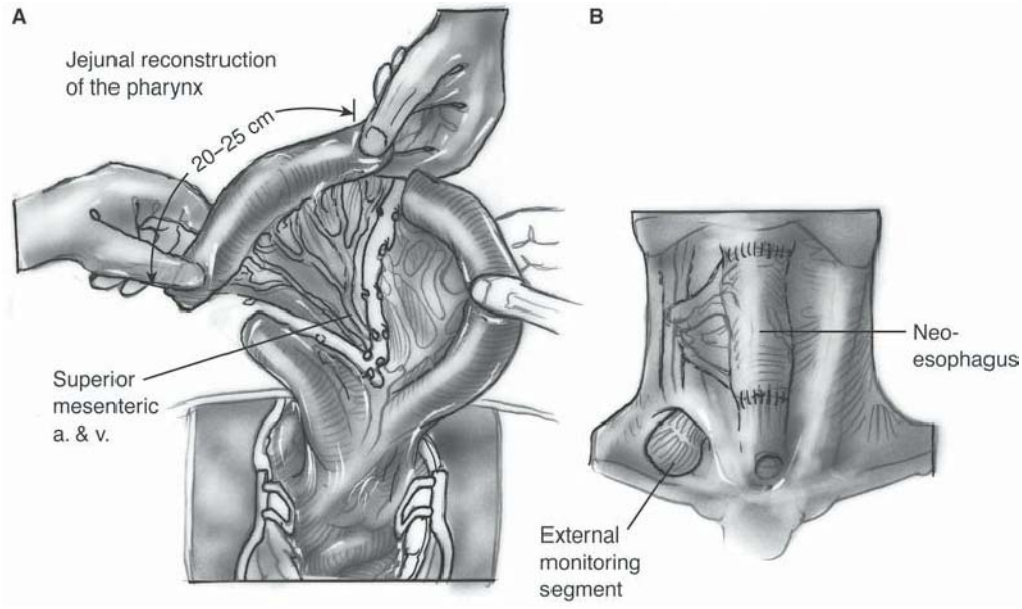

Figure 174.12 **A:** Segment of proximal jejunum of sufficient length supplied by a single arcade. **B:** The jejunum is shown as a segmental reconstruction of a total pharyngeal defect with a monitoring segment. The jejunum is inset under a minor degree of tension to reduce dysphagia.

Technical Considerations

A suture is placed at the proximal end of the graft at harvest to ensure isoperistaltic reconstruction of the pharyngoesophagus. Any redundancy of the jejunal segment is avoided to prevent dysphagia. The proximal end of the jejunum can be divided along the antimesenteric border to facilitate closure to the tongue base. The distal end of the jejunum is anastomosed in an end-to-end manner to the stump of cervical esophagus. Postoperative monitoring is facilitated by exteriorizing a monitoring segment of the jejunum. This segment is based on the same mesenteric arcade as the rest of the flap (40). This segment can be observed for peristalsis and evaluated directly with a Doppler probe.

Preoperative Considerations

Extension of disease into the proximal thoracic esophagus is an absolute indication for esophagectomy and colon interposition. The presence of ascites and chronic intestinal diseases such as Crohn disease and previous extensive abdominal surgery or intraperitoneal sepsis are all contraindications for the use of the jejunum. Patients with limited pulmonary reserve are at increased risk of morbidity after laparotomy.

Postoperative Management

The external monitoring segment of jejunum is removed at the bedside on postoperative day 7 by means of suture ligation of its mesentery.

Omentum and Gastroomentum

Description

The greater omentum is a double layer of peritoneum that hangs like a sheet from its main attachments to the greater curvature of the stomach and transverse colon (Fig. 174.13). The blood supply to this structure arises from the right and left gastroepiploic vessels, which course in the cephalic edge of the omentum where it attaches to the stomach. The omental free flap is very infrequently used in head and neck reconstruction but has been used for a variety of defects including coverage of large scalp defects,

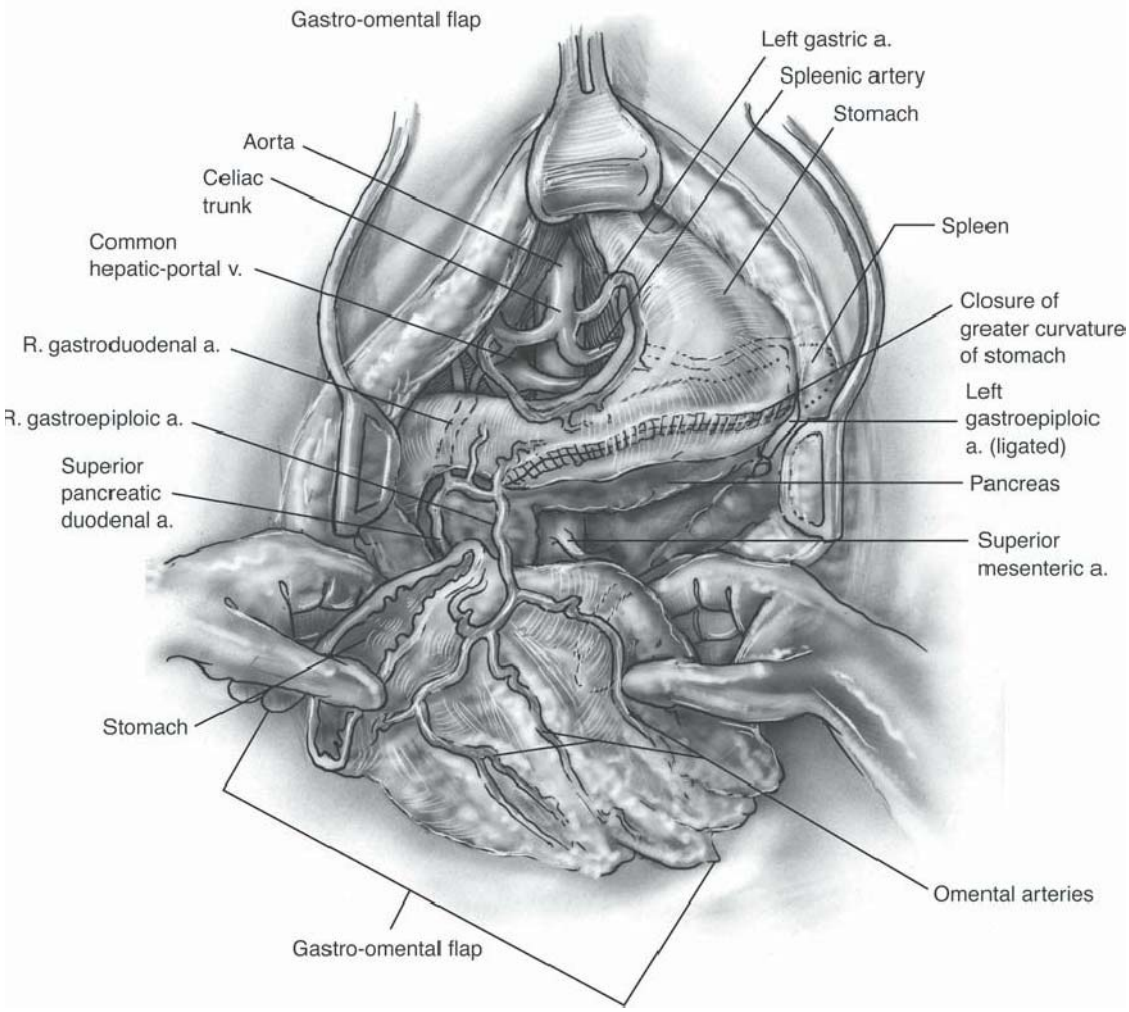

Figure 174.13 Gastroomental flap completely elevated from the greater curvature of the stomach.

repair of extensive midfacial defects with coverage of split rib or calvarial grafts, management of osteoradionecrosis and osteomyelitis in the head and neck region, and facial contouring. Although not used in North America, it has been used for severe cicatricial neck scarring after treatment of head and neck cancer with chemoradiation. Gastroomental autogenous transplants have been used for oral or pharyngeal defects; omentum is used to provide carotid coverage (41,42). The surgeon must carefully weigh the functional and aesthetic benefits of this flap against the risks of an intra-abdominal procedure. A recent application is its use as a tubed gastroomental transplant for the treatment of laryngopharyngectomy defects in patients who have failed treatment with chemoradiation. The perceived advantage is lower postoperative fistula rates, decreased neck scarring, and less postoperative structure (43).

Neurovascular Pedicle

The right gastroepiploic artery is more favorable for supplying omental flaps. The diameter of the right gastroepiploic artery ranges from 1.5 to 3.0 mm.

Potential Morbidity

A wide range of intra-abdominal complications can occur after harvest of a gastroomental free flap. The most serious is gastric leak with peritonitis and intra-abdominal abscess formation. Gastric outlet obstruction can occur if the harvest impinged *on the or is* placed too close to the pylorus.

Preoperative Considerations

A history of gastric outlet obstruction or peptic ulcer disease is a contraindication to this procedure.

MICROVASCULAR RECONSTRUCTIVE APPROACHES TO DEFECTS IN THE HEAD AND NECK

When reviewing various reconstructive approaches in the literature, it can be difficult to interpret results within a study or compare results between studies because there is no universally adopted system for coding head and neck defects. An effort has been made to classify defects on the basis of loss of epithelium, bone, nerves, and supporting musculature (44).

Pharyngoesophageal Defects

Pharyngoesophageal defects are classified according to circumferential involvement (partial, near total, and total) and whether the esophagus or a large portion of the oropharynx was included in the resection. Also important in determining the optimal reconstruction is consideration of the mechanism of postoperative voice production (tracheoesophageal puncture vs. electrolarynx) and the use of postoperative radiation therapy.

Partial pharyngoesophageal defects are divided into those that can be closed primarily with minimal risk of stricture and partial defects that require additional tissue for reconstruction to minimize the risk of stricture. In general, partial pharyngeal defects that require additional tissue for closure are those that have undergone sacrifice of at least 50% of the pharynx, such as one piriform fossa and 50% of the posterior pharyngeal wall, and primary closure cannot be performed without high risk of pharyngeal stenosis. Near-total pharyngoesophageal defects are defects in which only a thin strip of pharynx (1 cm) remains. Total pharyngeal defects are those in which there is complete absence of a segment of the pharynx and a circumferential reconstruction is required.

Partial pharyngeal defects that require additional tissue and near-total pharyngeal defects can be reconstructed with either pedicled regional flaps or free tissue transfer. The following factors are taken into account to assist in decision making: (a) There must be adequate vascular access for a free tissue transfer, (b) carotid protection is believed to be beneficial if a modified radical or radical neck dissection has been performed and a pedicled regional flap such as a pectoralis or latissimus dorsi flap can be used to provide carotid coverage, (c) for total or near-total pharyngeal defects, the soft tissue should be thinner than 2 cm.

For total pharyngoesophageal defects, four types of reconstructions are considered. A gastric transposition (this is a pedicled flap), colon interposition, autogenous jejunal transplant, and large autogenous cutaneous transplants such as radial forearm or an anterolateral thigh. It is technically possible to perform the majority of total pharyngeal reconstructions with an autogenous jejunal transplant or autogenous cutaneous transplant. If the defect extends into the mediastinum, preoperative consultation with a thoracic surgeon and planning of a colon interposition flap is appropriate. Gastric transpositions are no longer the best reconstructive option because they do not remain as well vascularized as the colon when extended up into the oropharynx and are associated with significant reflux (45).

The autogenous jejunal transplant was the first and the most commonly used donor site to reconstruct total pharyngoesophageal defects. The shortcomings are a wet voice, especially if the patient does not undergo postoperative radiation therapy, and dysphagia from autonomous peristalsis; halitosis; difficulty with reconstructing more extensive oropharyngeal defects; and the opening of the peritoneum. Cutaneous autogenous transplants (radial forearm, anterolateral thigh) have nearly replaced the jejunum as the reconstructive option of choice. The cutaneous donor sites can provide better voice, less dysphagia, and less donor-site morbidity compared to the jejunum. The trade-off with cutaneous donor sites is the higher incidence of stricture (46). Some surgeons use a salivary bypass tube at the time of surgery to reduce the likelihood of a stricture (47).

In addition to considering the size and the extent of the defect as discussed above, consideration of the quality of the tissue is important. In the situation of surgical salvage after failure of chemoradiation therapy, the fistula rate with primary hypopharyngeal closure is high. In an attempt to reduce the fistula rate, fasciocutaneous autogenous transplants are used as a pharyngeal interposition or onlay grafts. They are used to support the primary closure of hypopharyngeal defects and have been shown to decrease the fistula rate to 20% in a small case series (48). In a similar fashion, rotational muscle flaps can also be used as a source of unradiated, well-vascularized tissue to reduce the incidence of fistula. Another approach to the reduction of complications for patients undergoing salvage total laryngopharyngectomy is the autogenous gastroomental transplant. The inferior edge of the stomach is tubed for the pharyngeal reconstruction, and the omentum can be used to resurface the entire anterior neck skin as necessary.

Oral Cavity and Oropharyngeal Defects

In the oral cavity and oropharynx, microvascular reconstruction has improved function and reduced complications of the tongue and mandible (7). The sensate radial forearm autogenous transplant has become the workhorse of low-volume, soft tissue oral cavity reconstruction; the sensate lateral arm is an alternative for slightly larger-volume defects. Because of the ease of harvest and microvascular anastomosis, the anterolateral thigh has become the donor site of choice for larger-volume defects. Reconstruction of associated mandibular bony defects can compromise soft tissue reconstruction because the soft tissue associated with osseous donor sites is not as versatile as the soft tissue donor sites. When the functional results are likely to be compromised by use of the soft tissue component of an osseous transplant, two donor sites can be used. A soft tissue donor site and an osseous donor site can be combined to optimize speech, swallowing, and cosmetic results. An example is an angle-to-angle mandibular defect combined with two-thirds anterior glossectomy. A fibula autogenous transplant can be used for osseous reconstruction, and a soft tissue flap such as a perforator TRAM rectus, latissimus dorsi, anterolateral thigh, or a lateral arm can be used for the glossectomy reconstruction. For the repair of some of the largest soft tissue defects that include the entire tongue, musculocutaneous donor sites such as the rectus abdominis and latissimus dorsi are used.

The principles of oral cavity reconstruction are to obtain watertight closure; maintain mobility; provide sensation, including cable grafting of segmentally resected sensory nerves; maintain the volume of the resected tissue; maintain oral competence; and prevent medically significant aspiration. The radial forearm autogenous transplant is uniquely suited to reconstruction of the oral cavity when there is remaining functional anterior tongue. It is a thin, supple donor site of ample size to provide mobility. The antebrachial cutaneous nerve can be used to innervate the flap and provide cable grafts for the inferior alveolar or lingual nerves. Deepithelialized segments can be used to contour the reconstruction to restore the original shape of the resected tissue (49).

For total glossectomy defects a large volume of subcutaneous tissue is made into a mound to allow contact between the flap and the remaining sensate mucosa in the oral cavity. If a laryngectomy has not been performed, the hyoid bone must be resuspended to the mandible to help prevent aspiration.

Complex full-thickness defects (defects that include oral mucosa in continuity with external skin) usually are encountered in conjunction with mandibular defects. These defects can be reconstructed with a multipaddled osteocutaneous latissimus or scapula autogenous transplant or a combination of a soft tissue and a osteocutaneous fibular flap.

Midfacial Defects

Midfacial defects traditionally have been managed with a prosthesis. Revascularized free tissue transfer has been valuable in reconstructing the maxilla to maintain midfacial projection in the premaxillary, zygomatic, and infraorbital regions. It also has been useful in providing soft tissue to the cheek and orbit. The principles of midfacial reconstruction are to restore the contour and projection of the midface, to facilitate rehabilitation of an occlusal surface in the upper jaw, to provide oronasal separation, to close the orbit or provide a platform for prosthetic rehabilitation of the eye, and to maintain a functioning lacrimal system if the globe is intact. Use of a hard-palate obturator is an excellent approach to a maxillectomy defect, and that is limited to the ipsilateral secondary palate. When evaluating a patient for reconstruction of the midface, it is important to consider and coordinate the tissue transplantation with the prosthetic rehabilitation to optimize the functional and aesthetic results.

It is helpful to classify defects involving the maxilla. There are at least two classification systems that are helpful for thinking about maxillary reconstruction (50,51). These defects can be categorized first by dividing them into infrastructure (oral palate) and combined infrastructure and suprastructure defects (oral palate, maxillary buttresses, orbital rim, and orbit). Infrastructure (oral palate) defects can be approached with a wide variety of techniques. Combined infrastructure and suprastructure defects can be subdivided as follows: (a) maxillectomy with intact orbital rim, (b) maxillectomy including the infraorbital rim, (c) maxillectomy including the infraorbital rim and orbital contents, and (d) composite defects, which can include any of the other defects combined with facial skin. The principles to be addressed are midfacial projection, the infraorbital rim, orbital floor support, oral nasal separation, and a stable platform for mastication.

Maxillectomy defects with intact orbital rim that only involve two buttresses are effectively reconstructed with an obturator. The obturator provides adequate oronasal separation, a stable platform for mastication, and an anchor for additional teeth if the patient does not have an intact dental arch. Maxillectomy defects including infraorbital rim are best reconstructed with free tissue transfer, either alone or in concert with a prosthesis. An effective approach for patients without teeth or who cannot afford osseointegrated implants is vascularized bone osseocutaneous forearm autogenous transplant or a TDAST for the infraorbital rim reconstruction and orbital floor support in combination with a maxillary obturator to provide dental arch (52). For patients who can afford implants or whose remaining dentition is intact and healthy, an osseocutaneous flap such as an iliac crest, fibular, or TDAST in combination with osseointegrated implants as needed has become a more frequently used approach to avoid a maxillary obturator.

Maxillectomy defects including the infraorbital rim and orbital contents are much larger-volume defects. The principles to be addressed are the same as those for defects with an intact orbital rim with the additional issue of volume requirement for the orbital defect. A TDAST alone or an osseocutaneous radial forearm transplant in combination with a maxillary prosthesis can be used. Orbital prostheses usually are not accommodated in the primary reconstruction. A closed orbit is considered easier to manage and cosmetically superior by most but not all patients (9). Another alternative to reconstruction of these large defects is to obliterate the space with a large-volume soft tissue transplant such as an anterolateral thigh or a rectus. The approach does not restore the craniofacial skeleton or the dental arch, but it does prevent a sunken midface, provides oral nasal separation, and is much easier and reliable than the approaches with the osseous transplants (53).

The composite maxillectomy defect is relatively straightforward to reconstruct if a large soft tissue transplant is used to obliterate the resected volume. Multiple paddles are used to resurface the palate and the facial skin. If the craniofacial skeleton, the dental arch, and the soft tissue are anatomically restored for a patient with a composite maxillectomy defect, the reconstruction is much more difficult. Multiple paddles are used to resurface the palate and the facial skin. TDAST is the one of the most useful donor sites for the management of these complex defects if restoration of the craniofacial skeleton is desired (38). The osteocutaneous radial forearm is a distant second because of the small volume of bone stock and donor-site morbidity. The scapula donor site has adequate bone stock to recontour most maxillary defects, the soft tissue can be positioned independently from the bone, and there is ample subcutaneous tissue to recontour the cheek and fill the orbit as needed. This donor site is based on the subscapular and circumflex scapular artery is supplied by a pedicle that is much shorter than the latissimus dorsi artery pedicle that supplies the latissimus dorsi soft tissue and the tip of the scapula (TDAST). As a result, the TDAST is replacing the traditional subscapular/circumflex scapular donor site for the reconstruction of these defects.

Defects of the Base of the Skull

Microvascular reconstruction has been a key factor in facilitating skull base surgery. The rectus donor site has been used because of its bulk, long vascular pedicle (if the rectus muscle is included as part of the pedicle length), ability to make multiple skin islands by means of deepithelialization, and ease of patient positioning and ability to perform primary closure at the donor site. The disadvantage of use of a rectus flap is poor color match and a tendency toward ptosis. These cosmetic limitations of the myocutaneous rectus transplant decreased its use. As a result, the anterolateral thigh donor site has been used as an alternative if it can supply adequate volume to obliterate the defect. For thin patients, the rectus donor site may be the only site with adequate soft tissue. Obtaining adequate soft tissue is a common problem in breast surgery as well, and a perforator-based harvest technique borrowed from breast reconstruction that spares the rectus and reduces the problems with ptosis is useful for skull base reconstruction. It is likely that there will be increasing use of perforator-based rectus transplants for skull base reconstruction due to a long pedicle (15 to 18 cm), ample soft tissue, multiple paddles, and limited donor-site mobility. As for other craniofacial defects, the bone can be reconstructed; the functional and esthetic results are judged to be better, but these approaches are much more difficult. Calvarial defects can be reconstructed with split calvarial bone or hydroxyapatite compounds. Any area of bony projection should be reconstructed with vascularized bone if the patient has undergone or plans to undergo radiation therapy.

The principles of skull base reconstruction are to support the dural closure (separation of the cranial cavity from the upper aerodigestive tract), provide carotid coverage, obliterate dead space, support nonvascularized bone reconstruction, and restore calvarial and facial contour. The defects can be anterior or lateral defects. Anterior skull base defects that include the orbit and maxilla are best reconstructed with a large-volume flap such as a TDAST or a soft tissue flap (anterolateral thigh or rectus) if cosmesis and function are of secondary importance. Anterior defects limited to the fovea ethmoidalis or the orbitofovial defects with an intact maxilla that cannot be reconstructed with local flaps can be reconstructed with a thin, partially deepithelialized soft tissue transplant (radial forearm or anterolateral thigh). Lateral skull base defects are best reconstructed with a thick anterolateral thigh, lateral arm, or a muscle-sparing latissimus transplant. These flaps have better color match than the musculocutaneous rectus donor site and have a reduced tendency to become ptotic. The ideal donor site for color match and reduction of ptosis is the lateral arm donor site; this is also a good source of donor nerve. The challenge with the lateral arm donor

site is the small short pedicle. The same principles apply to skull base reconstruction with respect to prosthetic management. It is important to have the patient see the prosthetist prior to the surgical treatment to obtain the best functional and aesthetic results.

External Soft Tissue Defects

Autogenous tissue transplantation is useful in the management of massive cutaneous defects of the scalp or skin that cannot be reconstructed with local tissue or when reconstruction with a regional pedicled rotational flap gives suboptimal cosmetic results. The optimal flap for reconstruction is based on the site of the defect. For defects of the face and neck, the anterolateral thigh, scapular and lateral arm, and muscle-sparing latissimus donor sites are used because they have an adequate amount of subcutaneous tissue to allow contouring; the contour is stable and does not become ptotic. For scalp defects, the latissimus dorsi muscle with a split-thickness skin graft is used because it is thin, is tightly adherent to the skull, and easily allows fitting of a wig. Calvarial defects are recontoured at primary reconstruction, because it is difficult to close the latissimus dorsi muscle after secondary reconstruction of the calvarium. For forehead defects, a radial forearm flap is used most often, although the color match is poor. The principles of reconstruction of large soft tissue defects are to provide coverage of critical structures (large vessels, dura, or cranial nerves), restore the skeletal contour with split calvarial bone or hydroxyapatite paste, restore soft tissue contour, allow fitting of a wig as needed, and obtain optimal color match.

HIGHLIGHTS

- Revascularized free tissue transfer is a reliable and cost-effective approach to head and neck reconstruction.
- The evolution of microvascular free tissue transfer has advanced head and neck reconstruction. The technique enables the surgeon to perform exacting and sophisticated reconstruction and primary resection in a single stage.
- Free tissue transfer is most useful for management of sophisticated oromandibular reconstruction, total pharyngeal defects, complex midfacial defects, skull base defects, and large external soft tissue defects of the head and neck.
- The advantages of free tissue transfer are reliability, vascularity, abundant supply of high-quality tissue, potential for sensory and motor reinnervation, and inset into a heavily irradiated bed if necessary.
- The disadvantages of free tissue transfer are complexity, need for special instrumentation and training, increased operating time, and involvement of two surgical teams.
- Radial forearm free tissue transfer has become the workhorse of head and neck reconstruction because the flap is reliable, thin, pliable, and sensate and can be contoured to the defect.
- Musculocutaneous free tissue transfers are more bulky than fasciocutaneous flaps. The flaps are used for management of larger soft tissue defects such as those caused by total glossectomy or of large skull base defects.
- Selection of the osteocutaneous flap to be used for reconstruction depends on many factors, including vascular anatomic features, vessel quality, available bone, versatility of the soft tissue, donor-site morbidity, and feasibility of simultaneous two-team surgery.
- There is no ideal osteocutaneous flap for the management of combined bone and large-volume soft tissue defects.
- Pharyngoesophageal reconstruction requires careful preoperative assessment of extent of the tumor, consideration of method of voice rehabilitation, and the planning of radiation therapy before the reconstruction and surgical team can be chosen.
- When evaluating a patient for midfacial or skull base free tissue transfer, it is important to consider the integration of prosthetics to obtain the optimal functional and aesthetic results.

Tissue Expanders

175

Jonathan Liang *Jonathan M. Sykes*

The reconstructive ladder is a philosophical model used in facial plastic surgery to address cutaneous and soft tissue defects. The reconstructive ladder represents a graduated approach (Fig. 175.1), with closure via secondary intention as the most basic technique and closure with a microvascular free flap as the most complex technique. Tissue expansion falls in the upper middle tier of the reconstructive ladder. It is used when there is not enough adjacent tissue to close a defect primarily or with a local flap.

Tissue expansion is a technique used by plastic and reconstructive surgeons to cause the body to grow additional skin, bone, or other tissues. Tissue expansion also occurs naturally in the human body. It can occur as a normal physiologic process—the most classic example is pregnancy, during which uterine and abdominal tissue undergo remarkable expansion and enlargement. Also, it can occur as a pathophysiologic process, such as with large tumors that lead to concurrent expansion of the overlying skin and soft tissue. Examples of tissue expansion can be seen in many cultures. Certain populations have employed forms of tissue expansion to decorate, enhance, or mutilate facial or body structures. The Mursi tribe of Ethiopia incorporates giant decorative plates in the lower lip (Fig. 175.2). The Kayan woman of Myanmar, formerly Burma wears a series of rings around the neck to enhance linear growth (Fig. 175.3). Tissue expansion is also seen in more mainstream culture with the popularity of body art and piercings. Similar to the use of large wooden spools used in the Waorani tribe of Ecuador, the youth counterculture has adopted ear gauges to widen the ear lobe as an expression of body art.

In 1905, Codvilla reported the first use of tissue expansion for medical purposes to lengthen a femur (1). In 1957, Neumann provided the first report of expanding the skin using an inflatable balloon, used in the setting to reconstruct a helical defect (2). Tissue expansion is best known for its use in breast reconstruction. Radovan popularized tissue expansion for postmastectomy breast reconstruction (3). In the 1980s, studies investigating the histologic effects of tissue expansion elucidated the biology and physiology behind this emerging reconstructive technique (4,5). Argenta reported the first description of tissue expansion in the pediatric population in 1981 (6). Tissue expansion became a widely accepted technique in the 1980s and has continued to be a useful technique in the armamentarium of the reconstructive surgeon.

The advantages and disadvantages of tissue expansion are outlined below (Table 175.1). The ability to bring skin with near-perfect match in color and texture is a significant benefit when compared with skin grafts and pedicled or free flaps, which often transfer tissue that is not similar in texture, thickness, or color. There is also minimal or no donor site morbidity because no secondary defect occurs. Tissue expanders are also able to incorporate tissue with specialized function or adnexal characteristics. For example, tissue expansion in the setting of breast expansion is able to preserve superior sensation in the skin flaps. In the setting of tissue expansion in the scalp for treatment of alopecia, tissue expansion can incorporate hair-bearing flaps. One major disadvantage of tissue expansion is that it does involve multiple surgeries and/or office visits. There is a noticeable visible deformity during the expansion period, which can lead to physical and emotional burdens for the patient.

SKIN BIOMECHANICS AND TYPES OF EXPANSION

Human tissues exhibit dynamic effects when exposed to sustained pressure and expansion. A key understanding of the physical properties of the skin is needed to understand the changes in skin biomechanics during tissue expansion. *Tension* is a function of the elastic fiber network and varies with location and age. *Extensibility* is the response of skin

Both authors have no conflict of interest and adhere to ethical guidelines.

Figure 175.1 Reconstructive ladder.

Figure 175.3 Kayan woman of Myanmar, formerly Burma with concentric rings around the neck to enhance linear growth.

to mechanical forces. *Viscoelasticity* is the function of creep and stress relaxation. *Creep* is defined as a gain in skin surface area that results when a constant load is applied. In other words, it is the tendency of a solid material to slowly move or deform permanently under the influence of stresses. *Stress relaxation* is defined as a decrease in the amount of force necessary to maintain a fixed amount of skin stretch over time (7,8).

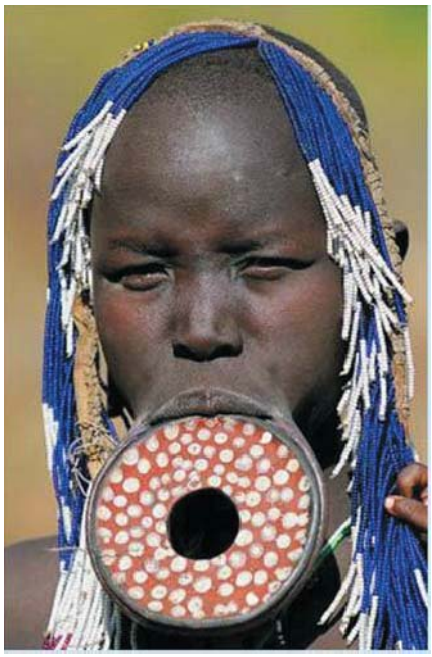

Figure 175.2 Mursi tribe woman of Ethiopia with a giant decorative plate in the lower lip.

The concept of creep is essential to understanding tissue expansion. There are different types of creep: biologic and mechanical (Table 175.2). Biologic creep involves permanent changes in the microanatomy of tissue. There is an overall increase in mitotic activity, with resultant net increase in surface area. In contrast, mechanical creep does not exhibit any change in tissue microanatomy. In mechanical creep, there is displacement of fluids and mucopolysaccharide ground substances, microfragmentation of elastic fibers, and alignment of randomly positioned collagen fibers into a more parallel position. There is no overall increase in mitotic activity and thus no net increase in surface area.

Biologic and mechanical creeps correspond to conventional long-term expansion and rapid intraoperative expansion, respectively (Table 175.3). In conventional long-term expansion, biologic creep is the underlying mechanism. It takes weeks to months to achieve and relies on physiologic and histologic changes in the tissue (9,10). Rapid

TABLE 175.1 ADVANTAGES AND DISADVANTAGES OF TISSUE EXPANSION

Advantages	Disadvantages
Skin with near-perfect match in color and texture	Involves multiple surgeries and/or multiple office visits
No or minimal donor site morbidity	Visible deformity
Tissue with specialized function or adnexal characteristics	Physical and emotional burden for patient

TABLE 175.2 TYPES OF CREEP

Biologic Creep	Mechanical Creep
Permanent changes in microanatomy	No change in microanatomy
Increase in mitotic activity	Displaces fluid and extracellular substances; collagen fibers realign
Net increase in surface area	No net increase in surface area

intraoperative expansion is a more controversial method of achieving tissue expansion. The underlying mechanism that occurs during rapid intraoperative tissue expansion is mechanical creep. There is rapid cyclical stretching of the tissue, which is performed often in a single setting, and results in only mechanical changes in the tissue (10,11).

PHYSIOLOGY

Maintaining living tissues under tension causes new cells to form and the amount of tissue to increase. An understanding of the skin microanatomy will help elucidate the changes that occur with biologic creep (Fig. 175.3).

The skin is composed of epidermis, dermis, and subcutaneous tissue (hypodermis). The epidermis is the uppermost layer and contains five sublayers (in order from superficial to deep): stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum, and stratum basale. The main cells found in the epidermal layer are Merkel cells, keratinocytes, melanocytes, and Langerhans cells. There are no blood vessels in the epidermis. The dermis is the middle layer and consists of a superficial papillary region and a deep reticular region. The papillary region contains loose areolar connective tissue, and the reticular region contains dense concentrations of collagen, elastic, and reticular fibers. The dermis contains many hair follicles, sweat glands, sebaceous glands, apocrine glands, lymphatics, and blood vessels. The subcutaneous tissue is the deepest layer of the skin and connects the dermis with the underlying bone or muscle—it supplies the underlying tissue with blood vessels and nerves. The main cell types in this layer are fibroblasts, adipocytes, and macrophages.

TABLE 175.3 TYPES OF EXPANSION

Conventional Long-Term Expansion	Rapid Intraoperative Expansion
Takes weeks to months to achieve	Rapid cyclical stretching performed in one setting
Physiologic and histologic changes occur	Mechanical changes only
Relies on *biologic creep*	Relies on *mechanical creep*
Well accepted	Controversial

With conventional long-term tissue expansion, biologic creep occurs at all levels of the skin. In the epidermis, there is an increase in mitotic activity. The thickness either stays the same or is slightly increased, and the stratified structure is preserved (10,12,13). The changes are temporary, and the microscopic appearance of the skin returns to normal within a year or two after the conclusion of expansion. In the dermis, there is significant thinning of approximately 30% to 50% (10,14,15). Of note, however, the basal layer actually thickens. There is increased metabolic activity in the fibroblasts and melanocytes with enhanced collagen synthesis and melanin production, respectively. The number of hair follicles and the pattern of hair growth remain the same, but the density of hair follicles decreases. Individual follicles may be separated by a factor of two without producing noticeable hair thinning. Given normal hair density, the scalp can be expanded by two to three times its original surface area before a change in hair amount is evident. In the subcutaneous tissue, adipose tissue thins approximately 50% with loss of adipocytes (14,15). There is also some muscle thinning and atrophy (15). Vascular proliferation occurs with the growth of capillaries, venules, and arterioles (16). Nerves lengthen with conventional tissue expansion, but their function is impaired (17). A dense fibrous capsule forms around the expander and contributes to the vascularity. The capsule also contributes to contracture and shrinkage of the flap after the expander is removed (18). The expander capsule thickness does not correlate with expander volume, location, or patient age (10).

APPLICATIONS

Tissue expansion has been used in breast reconstruction, closure of abdominal wounds, decubitus ulcers, extremity defects, burn scars, and even the separation of conjoined twins. In the head and neck, common applications include use in posttraumatic or postoperative alopecia, male pattern baldness, expansion prior to major reconstruction, congenital microtia, and large or giant melanocytic nevi (19–21).

Tissue expanders have been used in the scalp, forehead, ear, nose, cheek, and neck. Table 175.4 provides general expectations for flap advancement for a given expanded flap and various areas of the head and neck (20). The measurement of expanded flap width is measured across the base of the expander. Tissue expansion works best in locations where there is solid bony support under the expander balloon device, such as the scalp and forehead. The scalp is the ideal place for tissue expansion (22,23). The tissue is thick and vascular. The solid calvarium provides an ideal base for the expander. Approximately 50% of the scalp can be reconstructed with the use of tissue expansion (24).

TABLE 175.4 EXPECTATIONS FOR FLAP ADVANCEMENT FOR AN EXPANDED FLAP IN AREAS OF THE HEAD AND NECK

Site	Expanded Flap Width (cm)	Expected Flap Advancement (cm)
Scalp	12–16	Up to 8
Forehead	8–14	Up to 7
Midface	10–14	Up to 7
Ear	4–8	Up to 4
Neck	12–16	Up to 8

From Hoffmann JF. Tissue Expansion in the Head and Neck. *Facial Plast Surg Clin North Am* 2005;13: 315–324.

Use of tissue expanders for auricular defects is limited by the lack of adequate non–hair-bearing soft tissue in the adjacent area. Nasal reconstruction often requires an expanded midline forehead flap. The potential for contracture of an expanded flap and thickening of the tissue from the capsule may limit the application in reconstructing subunits of the nose where a thin and pliable soft tissue coverage is essential to allow the cartilaginous framework to show through. However, some surgeons do use tissue expanders in the forehead prior to elevating and transposing a forehead flap. In the cheek and neck, the skin is relatively thin and there is potential for damage to the facial nerve and underlying musculature with tissue expansion. Smaller volume expanders and longer-term expansion can be used to minimize complications. The gravitational forces in these areas can lead to the migration of expanders, and thus, the base often needs to be secured to the underlying structures.

EXPANDER DEVICES

Current tissue expanders are Silastic balloons (Fig. 175.4). Tissue expanders are defined by shape, size, and injection port.

Expanders can be rectangular-, circular-, or crescent-shaped. Custom sizes and shapes can be made for specific uses. For large scalp rotation flaps, crescent or circular expanders are ideal. For straight advancement flap, rectangular expanders are ideal. Rectangular-shaped expanders are able to achieve a gain of 38% in tissue surface area. Round or circular-shaped expanders are able to achieve a gain of 25% in tissue surface area. Crescent-shaped expanders are able to achieve a gain of 32% in tissue surface area (25).

Tissue expanders vary in size from 1 to 1,000 mL, with head and neck tissue expanders usually varying from 1 to 250 mL. The injection port can be remote, integrated, or external. For tissue expanders with an integrated injection port, a small butterfly needle (23 or 25 gauge) is commonly used for injecting the expander during the expansion phase. Most injection ports have a raised palpable ring. Some integrated expanders have a separate magnet

Figure 175.4 Tissue expanders. Expanders come in various shapes and sizes. These expanders have external ports, but tissue expanders with integrated ports also exist.

that helps to localize the injection port. As the volume of the implant increases, tension is distributed to the surrounding tissues, which results in their expansion over time. The advantage of internal versus external ports has been debated (26–28). The arguments for external ports are that they require less dissection, have painless port access, and allow for earlier detection of leaks.

Tissue expanders can also be classified by two-dimensional or three-dimensional expansion. Two-dimensional linear skin stretchers consist of a Dacron strip with hooks on both ends that are prestretched and placed under the previously elevated skin flaps—as the Dacron strip returns to its native size, it stretches the skin. Two-dimensional expansion creates forces by pulling the perimeter away from the central portion of skin being stretched (10). In contrast, three-dimensional expansion creates forces by pushing and compressing the skin away from a fixed perimeter (10). Three-dimensional expansion is the mainstay type of tissue expander.

SURGICAL TECHNIQUES: CONVENTIONAL LONG-TERM TISSUE EXPANSION

Strategies for use of tissue expanders vary from surgeon to surgeon. The stages of the tissue expansion process include selecting the ideal expander, inserting the expander, expanding the expander, and removing the expander with simultaneous reconstruction.

In selecting the most ideal expander for the patient, it is important to consider the size of the defect, location of the defect, and the goals of the patient. This is an important step in the preoperative assessment and preparation. General

principles include using the largest possible expander, and often more than one expander may be needed for large defects. A single large expander is preferred over multiple smaller expanders because this will give the greatest gain in tissue per volume of expansion and limit the number of operative sites. The surface area of the expander base should be 2.5 to 3 times as large as the defect size (20).

The actual surgery begins with placement of the expander. The incision for the placement should be as far from the expander as possible to prevent dehiscence during expansion and exposure of the device. A small V- or U-shaped incision placed radially (perpendicularly) related to the direction of expansion is ideal (29). In the scalp, the tissue expander should be placed between the galea aponeurosis and the pericranium. In the forehead, the tissue expander should be placed deep to the frontalis muscle. In the face, the tissue expander should be placed superficial to the superficial muscular aponeurotic system. In the neck, the tissue expander should be placed superficial to the platysma muscle (30). Nevertheless, wide undermining of the pocket for the expander is important in any of these locations. The expander pocket should be dissected wider than the base of the expander in a blunt fashion to preserve the longitudinal bloody supply (4). Furthermore, the expander pocket must be large enough to allow the expander to lie completely flat without any folding, buckling, or distortion.

The expansion phase is often the most burdensome for the patient—both physically and emotionally. The interval and volume of expansion may vary by region and wound type. Typically, 2 weeks are allowed for the wounds to heal after expander placement before the expansion phase begins. Serial inflation of the expander occurs over 4 to 6 weeks. Expansion should be continued until the extended flap is approximately 20% larger than the size of the defect to account for tissue recoil during advancement. Inspection of the skin color (blanching), capillary refill, and direct palpation are routine when evaluating for further expansion. When the patient experiences any significant pain during expansion, the injection should be stopped and saline should be removed. Overinflation of the tissue expander beyond the manufacturer's recommended fill capacity is common in clinical practice (31), and one study has shown overinflation associated with lower complication rates (32).

The final step in the process involves removal of the tissue expander device and simultaneous reconstruction with the expanded flap.

Case 1

A 2-year-old girl with a hairy nevus of the anterior scalp. The lesion was present at birth and has grown proportional to the patient's growth. Examination showed a 5 × 6-cm well-circumscribed mass at the frontal hairline that is hyperpigmented (Fig. 175.5). The patient underwent conventional long-term tissue expansion. During the insertion phase, the selected tissue expander was placed in an area just posterior to the lesion between the galeal and pericranial layers of the scalp (Fig. 175.6). During the expansion phase, the patient underwent a series of five expansions over the course of 6 weeks to a final volume of 110 mL (Fig. 175.7). During the removal and reconstruction phase, the tissue expander was removed and the expanded skin was advanced to the edge of the defect site (Fig. 175.8).

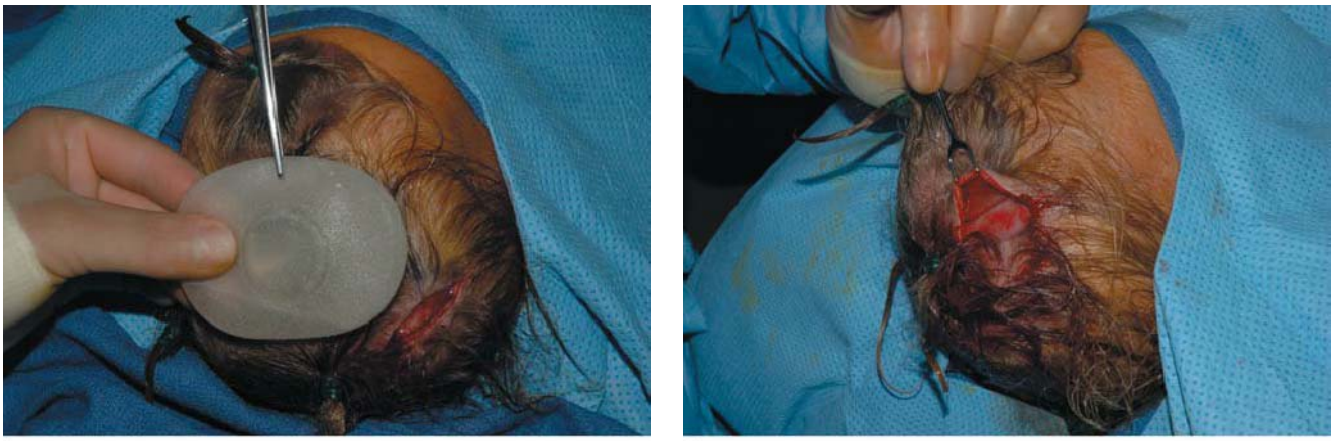
Figure 175.5 Pediatric patient with hairy nevus of anterior scalp.

Case 2

A 38-year-old woman with a neck scar from a burn injury as a child who had undergone previous revision and laser treatment with persistent scar deformity. Examination showed a horizontally oriented 10 × 3-cm hyperpigmented scar with mild wound contraction around the edges (Fig. 175.9). The patient underwent conventional long-term tissue expansion. During the insertion phase, a circular tissue expander was placed in the neck superior to the scar site in the plane above the platysma muscle. During the expansion phase, the patient underwent a series of expansions over the course of 8 weeks to a final volume of 80 mL (Fig. 175.10). During the removal and reconstruction phase, the tissue expander was removed and the expanded skin was advanced inferior over the defect site (Fig. 175.11).

SURGICAL TECHNIQUES: RAPID INTRAOPERATIVE TISSUE EXPANSION

The protocols and principles discussed above apply to conventional long term tissue expansion. The protocol for rapid intraoperative tissue expansion significantly differs. This method has been championed by Sasaki (33,34).



A B

Figure 175.6 **A, B:** Insertion phase. An incision is made in the right posterior scalp, and a subgaleal pocket was created. A large oval-shaped tissue expander was selected to fill the planned defect site (**A**). The expander was placed in the subgaleal pocket just posterior to the lesion (**B**).

The phases are the same—selecting the ideal expander, inserting the expander, expanding the expander, and removing the expander with reconstruction. However, all this occurs in a single setting and relies on mechanical creep. There are no physiologic or metabolic changes that are seen in the setting of conventional long-term tissue expansion. A gain of 1 to 3 cm of flap length can be achieved, depending on the site of expansion. Table 175.5 provides rough estimates of the degree of lengthening one might achieve in some areas of the head and neck (34). During the expansion phase, the expander is inflated for 3 minutes and then deflated for several minutes. This process is repeated at least two more times. This is immediately followed by incision, inset, and closing of the flap. The process remains controversial. Critics of this technique have claimed that rapid intraoperative tissue expansion is simply augmented undermining and tissue rearrangement (35,36).

Figure 175.7 Expansion phase. The same patient during the expansion phase. The patient underwent a series of expansions for a total volume of 110 mL.

COMPLICATIONS

The reported complication rate with tissue expanders is approximately 10% (20,37,38). These complications include expander exposure or extrusion, skin necrosis or ischemia, numbness or weakness, infection, bone resorption, hematoma or seroma, and failure of the expander device. Most authors would advocate that exposed expanders can be watched, with cessation of interval expansion. However, it is often recommended that extrusion should be an indication for prompt removal. If there is evidence of skin necrosis or infection, the tissue expander should be removed, with culture and debridement of the wound. Careful antiseptic techniques should be observed to minimize infection around the devices.

CONCLUSIONS

Tissue expansion can be a useful technique in the armamentarium of a reconstructive surgeon. It can provide additional skin with similar characteristics and avoid unnecessary donor site morbidity. Tissue expanders are especially useful for reconstructing scalp and forehead defects, and its use has been described for all areas in the head and neck. The more traditional and commonplace conventional long-term tissue expansion relies on biologic creep and results in important physiologic changes at the epidermis, dermis, and subcutaneous tissue. Conventional long-term tissue expansion can be a lengthy process for both the patient and surgeon. There are many critics of rapid intraoperative expansion, but its main advantage is completing all the stages of tissue expansion in a single setting to minimize patient morbidity. There are many ongoing studies investigating new agents to help increase the rate of tissue expansion, and further research on both the mechanical and biologic properties of tissue expansion will help improve clinical outcomes of reconstruction with tissue expansion.

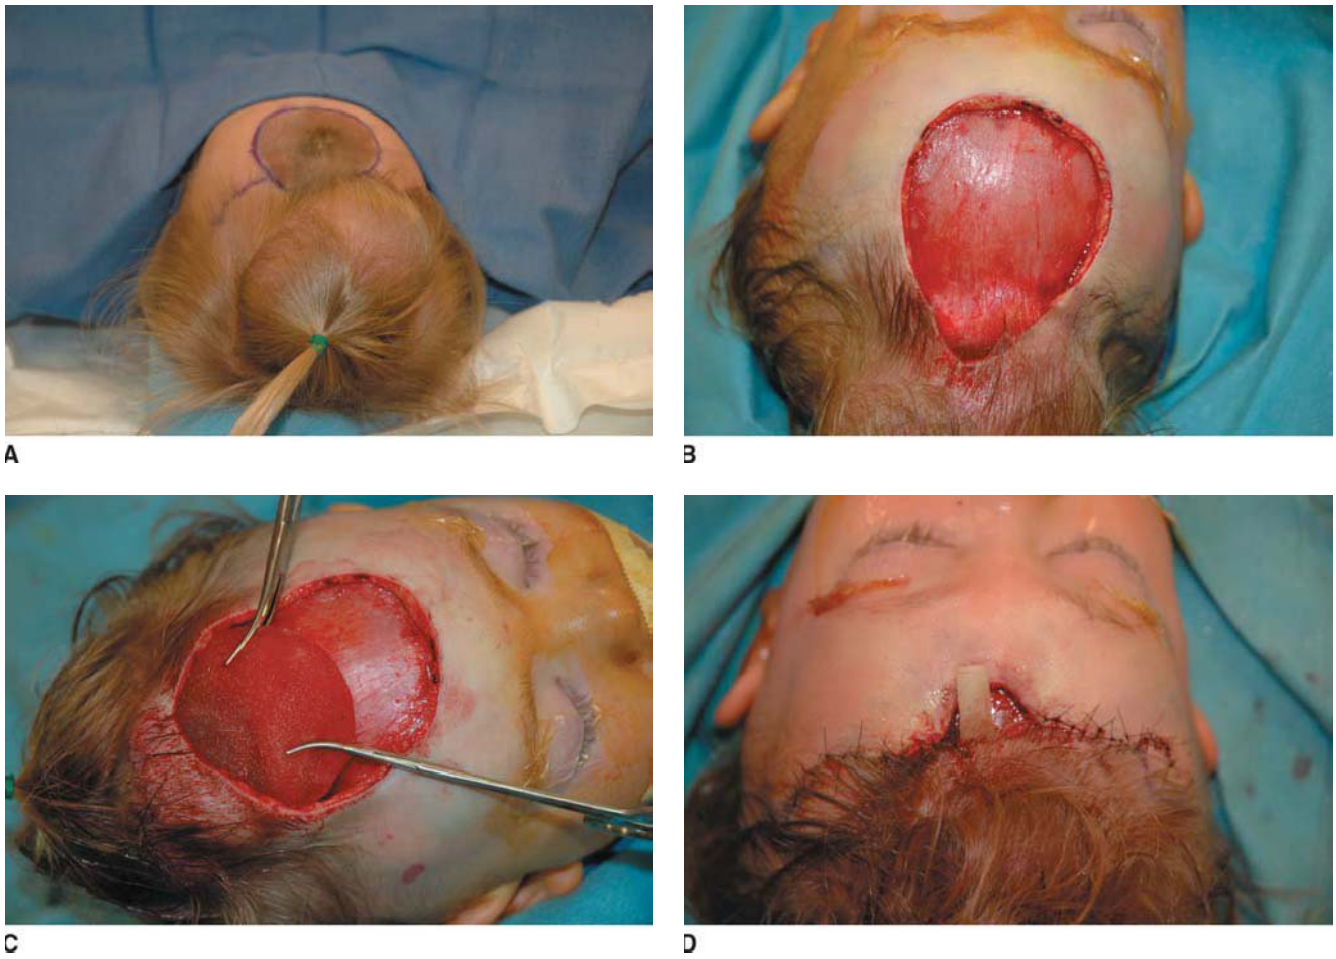


Figure 175.8 **A–D:** Removal and reconstructive phase. The area over the hairy nevus was shaved, and markings were made around the lesion site **(A)**. The hairy cell nevus was excised with minimal margin **(B)**. The tissue expander was dissected from the fibrous capsule, deflated, and removed **(C)**. The expanded scalp tissue was advanced to the defect size—the incision closed primarily laterally—and a small central area was left to granulate **(D)**.

The tissue expander was dissected from the fibrous capsule, deflated, and removed **(B)**. The expanded neck tissue was advanced to the defect size, and the incision was closed primarily **(C)**.

TABLE 175.5 ESTIMATED DEGREE OF LENGTHENING IN INTRAOPERATIVE TISSUE EXPANSION

Site	Average Tissue Gain per Expander (cm)
Scalp	1.9–1.5
Forehead	1.0–2.5
Upper nose	1.0–1.5
Nasal tip	0.50–0.75
Midface	1.0–2.5
Neck	1.0–2.5

From Sasaki GH. Intraoperative sustained limited expansion as an immediate reconstructive technique. *Clin Plast Surg* 1987;14:563–573.

HIGHLIGHTS

- Tissue expansion lies in the middle rung of the reconstructive ladder. It can provide skin with similar characteristics and avoids donor site morbidity.
- Conventional long-term expansion relies on biologic creep.
- Rapid intraoperative expansion relies on mechanical creep.
- Important physiologic changes in conventional expansion include increased mitotic activity and vascular proliferation.
- Various sizes, shapes, and types of tissue expanders exist. Rectangular expanders provide the largest gain in surface area. The base of the expander should be 2.5 to 3 times the size of the defect.
- The scalp and forehead are optimal sites for reconstruction with tissue expanders.
- Stages of tissue expansion include insertion, expansion, and expander removal with simultaneous reconstruction.
- Complications occur in approximately 10% of cases, with the most common of being expander extrusion or exposure.

Scar Camouflage

176

Shawn M. Stevens *Krishna G. Patel*

Scar camouflage constitutes one of the primary roles of the facial plastic surgeon, and in no other location of the body does this bear such aesthetic importance. The surgeon must possess a sound understanding of prevention and tissue handling techniques, as well as a fundamental understanding of wound healing and patient-specific risk factors in scar formation. Additionally, a wide array of techniques must exist within the surgeon's armamentarium, both surgical and nonsurgical, in order to appropriately manage the high variability of scar presentations (Table 176.1).

The surgeon's goal should be to select the best technique(s) for the individual patient and scar. This constitutes a challenging decision backed by a relative paucity of high-level evidence. Well-designed, comparison-controlled trials of various interventions are lacking for reasons including the following: (a) objective markers of scar improvement (color, elevation, texture) are inconsistent between studies; (b) interpatient scar variability makes adequate controls impossible; and (c) subjective scales such as patient and physician satisfaction scores are prone to significant inter- and intragroup variability (1). Despite these difficulties, strong trends do exist within the literature regarding surgical approaches to scar camouflage. Thus, the goal of this chapter is to provide the reader with a sound, evidence-based review of the available interventions for scar camouflage.

BASIC SCIENCE

Wound Healing

The wound healing process can effectively be broken into three distinct but overlapping phases: the inflammatory phase, the proliferative phase, and the remodeling phase.

The inflammatory phase (immediate onset lasting 2 to 5 days): This initially begins with hemostasis over the first 5 to 10 minutes via vasoconstriction and activation of the clotting cascade. This includes platelet aggregation and deposition of thrombin and fibrin. Vasodilation follows and peaks at approximately 20 minutes before vascular tone returns to its baseline. Also beginning immediately, aggregating platelets and local phagocytic cells (predominantly neutrophils for the first 24 to 48 hours) release a variety of proinflammatory and chemotactic cytokines. This in turn leads to an influx of macrophages. These are the essential mediators of early wound healing and predominant cell type from 48 hours through the remainder of the inflammatory phase. The macrophages for their part phagocytize bacteria and damaged tissue and release their own milieu of cytokines, growth factors, and chemotactic agents. This subsequently promotes the arrival of fibroblasts, endothelial and epithelial cell migration, and wound contraction by myofibroblasts.

The proliferative phase (day 2 through 3 to 4 weeks): Fibroblasts enter the wound around day 2, which signifies an overlap period of the inflammatory and proliferative phases. As the inflammatory phase ends and macrophages decline in number, fibroblasts take over as the predominant cell type. Through the resulting fibroplasia, granulation tissue forms, and extracellular matrix (ECM) is deposited consisting of disorganized collagen (mostly type III), elastin, and fibronectin. Angiogenesis and wound contraction (both begin around day 4) follow and are mediated by endothelial cell migration and wound margin myofibroblasts, respectively. Wound contraction is maximal around days 12 to 15. Reepithelialization also occurs during this phase through migration of epithelial keratinocytes from the wound margins and the bases of pilosebaceous subunits preserved in the wound at the level of the dermis. The process occurs best over a moist surface of viable tissue. This underscores the importance of a moist wound environment that not only aids migration but also prevents excess scabbing that acts as a barrier to migration. Reepithelialization ceases when the opposing sheets of migrating epithelial cells meet and reestablish contact inhibition.

TABLE 176.1 UNDESIRABLE SCAR TYPES

Atrophic scars (depressed)
Hsc (protrusive)
Irregularly shaped scars
Scars with color mismatch
Scars that cross RSTL/aesthetic subunits
Contracted scars that distort surrounding tissues
Keloids

RSTL, relaxed skin tension lines.

The remodeling phase (3 weeks to 2 years): Collagen remodeling occurs with fibers becoming aligned in a more parallel fashion and type I collagen being deposited in greater proportion. Excess cells are removed via apoptosis and phagocytosis. Also during this phase, the wound's tensile strength will increase roughly according to the following progression: 15% of original strength by 3 weeks, 60% by 6 weeks, and 80% by 3 to 6 months, which is the maximum achieved (2).

Deregulation or interruptions of this wound healing process, including interventions by the surgeon, can lead to alterations in the scar that ultimately forms. Other systemic and/or external processes including malnutrition, diabetes mellitus, smoking, excessive sun exposure, and immunosuppression can severely impede this process and lead to poor wound healing and worsened outcomes.

Scar Types

Scars can be classified broadly into hypertrophic scars (Hsc)/keloids and non-Hsc (1). Hsc and keloids are quite similar in nature and represent an aberration in the wound healing process. Patients prone to these types of scars have been shown to have down-regulation of various apoptotic genes and overexpression of signaling factors such as IL-6 and TGFβ1 and β2. Resulting histologic findings include ECM overproduction and deposition of highly disorganized collagen by hypermitotic fibroblasts (2,3). Keloids, by definition, are elevated fibrous scars that extend beyond the borders of the original wound, do not regress, and usually recur after excision. They can take between 3 months and years to develop. Hsc develop quicker (within 8 weeks), are confined to the wound borders, and usually will regress over a period of 12 to 18 months (2,4). Risks for keloid formation include darkly pigmented skin (15- to 20-fold increase), familial predisposition, and high wound tension. Hsc are less likely to be related to skin pigmentation. Care must be taken by the surgeon when working with patients at risk for keloid formation as there is a very high rate of recurrence, especially when surgical excision is used alone (5).

Non-Hsc can be divided into either atrophic (depressed) scars or scars that are flat or protrude minimally above the level of the adjacent normal skin (1). While less prone to recurrence and complications than keloids and Hsc, these scars can nonetheless be disfiguring and challenging to treat. The pathophysiology of this scar type is likely related to a hypoxic wound environment, abnormal levels of cellular apoptosis, and limited angiogenesis. The ultimate result is reduced deposition of ECM and collagen and a depression of the wound bed with regard to surrounding normal skin. Similar to keloid and Hsc, excessive tension on wound edges increases risk of atrophic scar formation.

SURGICAL TECHNIQUES

Surgical Planning and Scar Relocation

Four main factors exist that cause unsatisfactory scarring. These are (a) the direction of the scar with respect to relaxed skin tension lines (RSTLs) and if there is disruption or distortion of aesthetic units; (b) the uninterrupted length of a straight scar especially if greater than 2 cm; (c) an irregular texture to the scar surface; and (d) a color mismatch between the scar and surrounding normal tissues. Many techniques exist to treat these problems. In general, the goal is to achieve relocation, excision, irregularization, and/or disruption of a scar (Table 176.2). When planning to camouflage a scar, it is of critical importance to examine the scar's relationship to the facial aesthetic units, their borders, and the general locations of RSTLs (Fig. 176.1). Facial aesthetic units include the forehead, eyelids, nose, cheeks, lips, and chin. Aesthetic borders between or at the margins of these units are excellent locations for incision placement or scar relocation and include the hairline, infraorbital rims, nasofacial grooves, melolabial folds, vermilion borders, and preauricular sulci. Careful acknowledgment of RSTLs is important, as an incision or closure that crosses these at an angle greater than 30 to 40 degrees will produce an aesthetically displeasing result. With careful planning, many scars can be excised via fusiform incision/primary closure and achieve excellent results. Thus, one of the ideal camouflage techniques is achieved by placement of incisions within existing skin folds produced by RSTLs (6–10).

Scars or defects near the center of an aesthetic unit, resting over a convexity or concavity, or of great length make simple excision less effective. If extensive undermining of surrounding tissue is necessary for tension-free closure or the anticipated closure will distort a free margin of

TABLE 176.2 CHARACTERISTICS OF AN IDEAL SCAR

Thin width
Surface flush with surrounding skin
Color matches surrounding skin
Runs parallel to RSTL or along aesthetic subunits
Irregularized if long length

RSTL, relaxed skin tension lines.

Figure 176.1 Schematic illustrating the RSTLs of the face. (Modified illustration from Larrabee WF, Sherris DA. Soft tissue biomechanics and physiology. In: Larrabee WF, Sherris DA, eds. *Principles of facial reconstruction*, Chapter 1. New York: Lippincott-Raven, 1995:3.)

the face (lid, lip, nose) and/or cross an RSTL, alternative interventions should also be considered, such as local flap reconstruction (11).

Flaps

Flaps can be classified in a number of ways. Classification can be based on vascular supply, composition, and/or design and method of transfer (Table 176.3). Practical use often employs a combination of the above. Transposition flaps and local advancement flaps constitute the principle techniques utilized for scar camouflage. When performed correctly, these procedures can achieve excellent irregularization or disruption of a scar and provide near perfect color and texture match to surrounding healthy skin (8). The most commonly used techniques include the Z-plasty, W-plasty, and geometric broken line closure (GBLC) and will be discussed in detail below. Multiple variations of these techniques also exist and can be tailored to the individual patient and scar.

Z-plasty

One of the most common and important techniques in a surgeons' armamentarium is the Z-plasty transposition flap (Fig. 176.2). The basic Z-plasty can provide excellent cosmesis for a variety of scar revision purposes and is chiefly used to (a) lengthen a scar, (b) release a contracture, (c) disrupt a scar, or (d) realign a scar within an RSTL (Fig. 176.3). However, performing a Z-plasty also has its drawbacks. Lengthening the scar in one direction will result in shortening of the perpendicular direction, and a total of three scars must be made in the place of one.

TABLE 176.3 FLAP CLASSIFICATION SCHEMES

Classification	Subclassification	Subtypes	Examples
Vascular supply	I. Random supply		The majority of local flaps
	II. Axial supply (by named vessel)	A. Local	a. Paramedian forehead (supratrochlear artery)

		E. Free tissue transfer	e. Latissimus, scapular, radial forearm, etc.

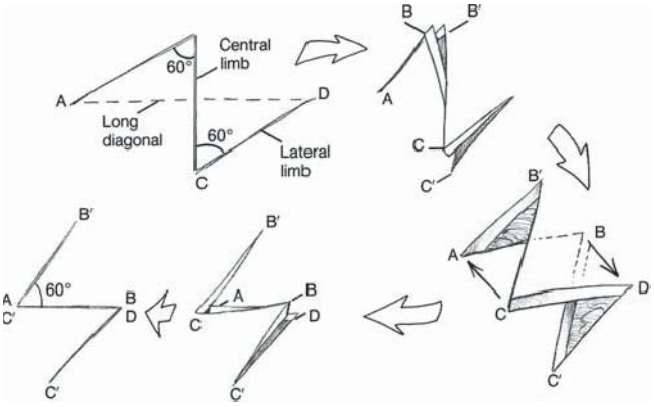

Figure 176.2 Classic design of the Z-plasty with 60 degree limbs. (From Hochman M. Scar Camouflage. In: Bailey BJ, Calhoun KH, eds. *Bailey-head and neck surgery—otolaryngology*, Chapter 166, Figure 166.3, 3rd ed., Vol. 2. New York: Lippincott Williams & Wilkins, 2001:2115.)

Technique—The traditional Z-plasty has two constant features. First, three incisions of equal length are made, one central and two limbs. The central incision, ideally, is designed to run parallel to the scar's long axis. Upon closure, the central component of the incision will achieve the greatest directional change, which makes careful planning of the central limb vital when attempting to realign the scar with an RSTL (Fig. 176.4). Most often, the defect left by a fusiform excision of the entire scar itself (or other defects such as that left by Mohs surgery) forms the central limb of the Z-plasty (11). The second feature is the two angles made by the limb incisions. In the traditional Z-plasty, these angles are equal and 60 degrees from the center. This results in the formation of two triangular skin flaps. When raised in the subcutaneous plain, the triangle tips are transposed such that the shared sides of the triangles approximate the skin side of the opposing limb incisions.

The effect achieved is a disruption of the scar itself and reorientation along the lines of the limb incisions, which do not move appreciably and should ideally be drawn within RSTLs. It is critical to note that if the initial scar was already oriented with an RSTL, the central incision will fall perpendicular to the same RSTL. Scars angling less than 40 degrees from an RSTL are often better managed with simple excision. A final important feature of the Z-plasty is that intelligent angle design allows the surgeon to anticipate the new length and degree of reorientation achieved after closure. The simple rule of thumb is that the 60-degree Z-plasty will produce a 75% increase in length and 90 degrees of rotation (Fig. 176.5). A change in angle produces predictable change of these variables (Table 176.4). If further lengthening is desired, serial Z-plasty can be performed (6,11). Of note, angles should never be less than 30 degrees as the flap tips will risk ischemia and necrosis.

A number of variations of the traditional Z-plasty exist including double-opposing Z-plasty, unequal triangle Z-plasty, four-flap Z-plasty, compound Z-plasty, and planimetric Z-plasty (6).

W-plasty

One of two common advancement flaps used for scar irregularization, the W-plasty produces a regularly irregular incision and should be used on long straight scars. Such scars reflect light homogenously and are easy for the eye to follow. Irregularization scatters that reflected light making it less visible to the observer. W-plasty is best suited for scars angling greater than 35 degrees from RSTLs or for scars that cross unforgiving areas of convexity or concavity (12). Unlike the Z-plasty, this technique does not increase the length of the scar. W-plasty is faster to perform than GBLC but forms a more predictable and conspicuous scar. As in GBLC, some normal tissue is removed, which increases overall tension on the wound.

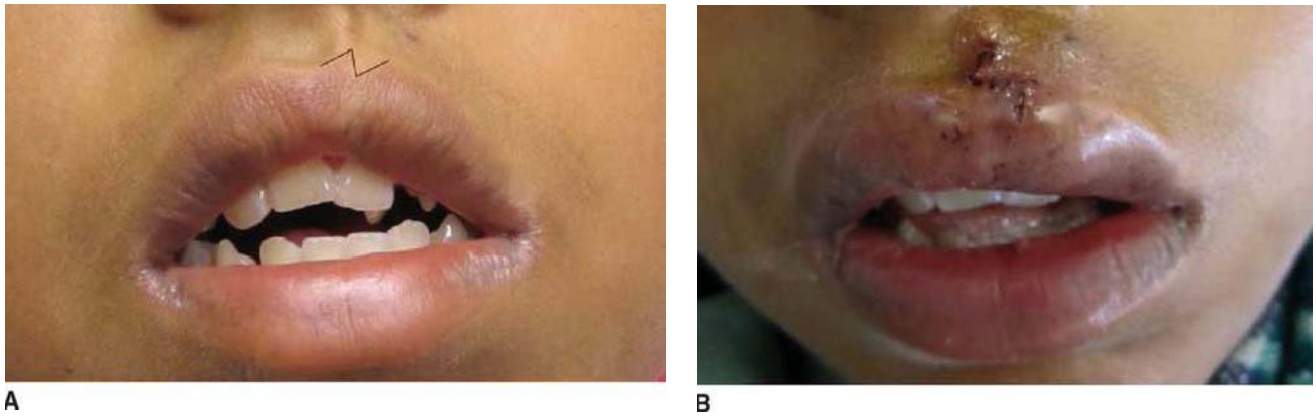

Figure 176.3 Patient with a history of cleft lip repair, who demonstrated a vermilion-cutaneous step-off deformity. Z-plasty technique was utilized to correct the step-off deformity and to realign the vermilion along the natural aesthetic border. **A:** Preoperative photo demonstrating the misalignment of the vermilion and skin of the upper lip disrupting the normal border of the lip vermilion subunit. Lines mark the planned limbs for the Z-plasty transposition flap. **B:** Immediate postoperative photo demonstrating the correction of the vermilion border and restoration of the natural cupids bow contour.

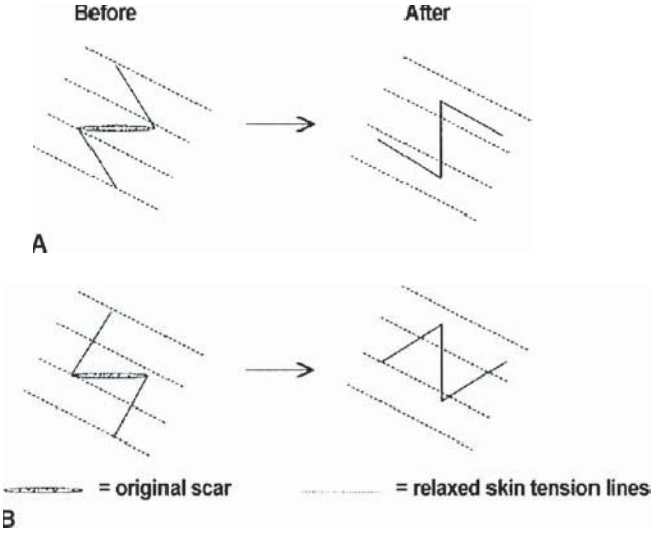

Figure 176.4 Schematic of Z-plasty technique that illustrates the importance of limb design. **A:** Preferred limb design that allows the final incisions to mostly orient parallel with the RSTLs. **B:** Poor limb design that causes the final incisions to orient across the RSTLs. (From Shockley WW. Scar revision techniques. *Oper Tech Otolaryngol* 2011;22:84–93, Figure 7, p. 89.)

Technique—The W-plasty is essentially a series of mirrored triangular advancement flaps (12) (Fig. 176.6). The apices of the triangles are placed 3 to 5 mm on either side of the scar, and each apex should be 5 to 6 mm apart from those adjacent. Limb length should be between 3 and 6 mm. Smaller limbs tend to not break up the scar adequately, while larger limbs form more conspicuous scars. The angle of each apex is designed individually to orient the limbs with RSTLs (Fig. 176.7). The ends of the incision are "closed" with a final set of triangles measuring 30 degrees or less. Anything larger can create a "dog ear" or "standing cone" deformity at the incisional margins. Alternatively, an

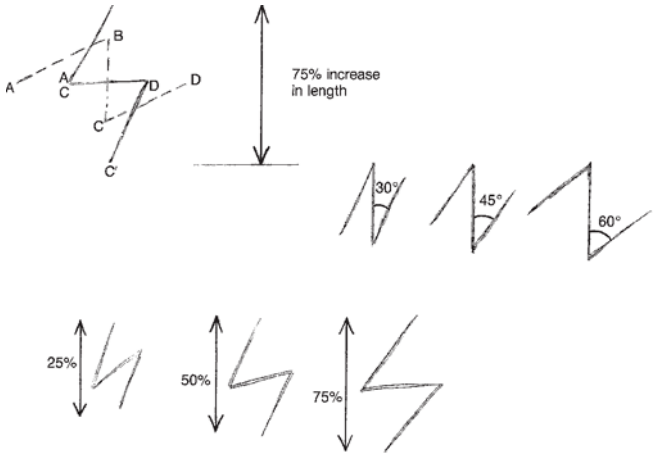

Figure 176.5 Schematic demonstrating how increasing the limb angles of a Z-plasty predictably increases the total final length of the scar. (From Hochman M. Scar Camouflage. In: Bailey BJ, Calhoun KH, eds. *Bailey-head and neck surgery—otolaryngology*, Chapter 166, Figure 166.4, 3rd ed., Vol. 2. New York: Lippincott Williams & Wilkins, 2001:2116.)

TABLE 176.4

Z-plasty Angle	Increase Central Scar Length	Central Scar Reorientation
30°	25%	45°
45°	50%	60°
60°	75%	90°
75°	100%	–
90°	125%	–

M-plasty can also be used to avoid extending the incision further. With traction applied, the W-plasty design is excised taking both scar and normal tissue with it. Closure is performed in layers.

Geometric Broken Line Closure

More complex and time consuming than the W-plasty, GBLC produces an irregularly irregular incision that maximizes scar camouflage. This technique is ideally used on scars that are relatively long and angle 45 degrees or greater from RSTLs. While GBLC has superior camouflaging results, it also carries a high degree of technical difficulty and significantly increases operative time (Fig. 176.8).

Technique—GBLC incorporates a series of advancement flaps in the form of opposing semicircles, squares, triangles, rhomboids, and rectangles in varying order and size (Fig. 176.6). The key feature is randomness of the design, which is difficult for an observer's eye to track. As is always the case, it is important to align straight portions of the new scar with RSTLs whenever possible. Individual flap length should fall between 3 and 7 mm, as greater lengths become too visible and smaller ones become difficult to close (Fig. 176.9). Flaps should be meticulously mapped out 3 to 6 mm from the scar margins, and the triangular ends of the design should again be less than 30 degrees to avoid a standing cone deformity. The design is excised under tension taking the interposing scar and normal skin. Due to forces across the wound bed, wide undermining may be necessary to assist in tension-free closure. Closure is achieved in layers similar to the W-plasty (12).

Serial Excision and Tissue Expansion

Serial Excision

This technique involves partial excision of a scar combined with undermining and advancement of the adjacent healthy skin. It requires a series of sequential procedures, but will eventually excise the scar completely. While not often used in scar camouflage, serial excision may be considered if the size and elasticity of a scar or tension

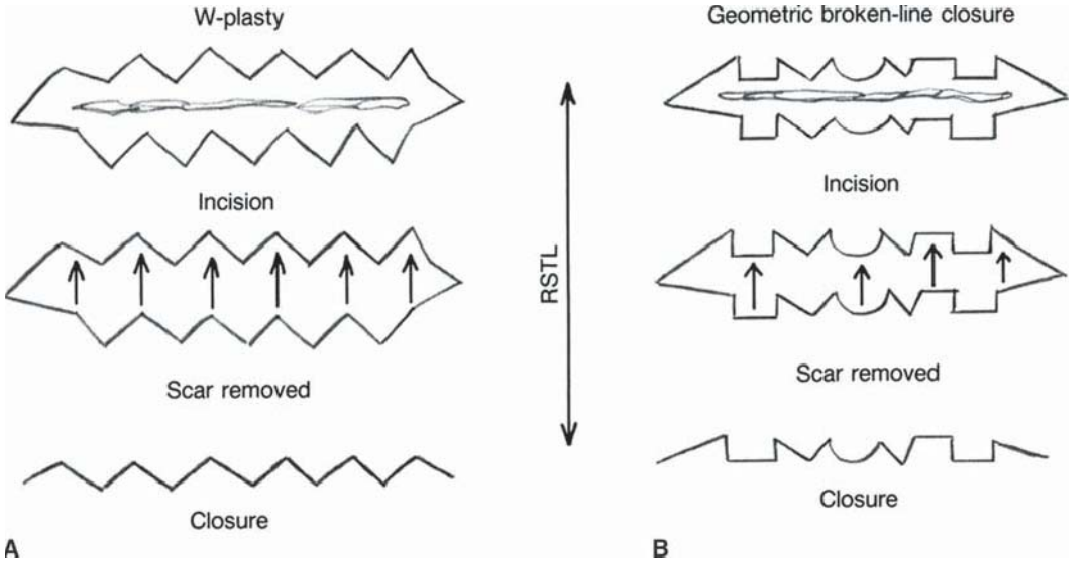

Figure 176.6 Schematic illustration of the W-plasty **(A)** and GBLC **(B)** techniques. W-plasty produces a regularly irregular incision through the advancement of serial triangular flaps. GBLC produces an irregularly irregular incision through the advancement of multiple geometric-shaped flaps. (From Hochman M. Scar Camouflage. In: Bailey BJ, Calhoun KH, eds. *Bailey-head and neck surgery—otolaryngology*, 3rd ed, Vol. 2, Chapter 166, Figure 166.6. New York: Lippincott Williams & Wilkins, 2001:2116.)

forces across the wound bed preclude a single excision and closure. The number of required excisions depends on the features of the scar. Between procedures, the available skin at the wound margin will increase via mechanisms of mechanical and biologic creep. This effectively increases the available tissue for the next stage of the excision. The primary disadvantage is the necessity for multiple operations (13).

Tissue Expansion

Tissue expansion represents another technique geared toward increasing available tissue for a planned future revision. It involves the placement of an implant under normal tissue adjacent to the scarred wound, followed by sequential office visits to expand the implant with saline injections. This in turn stretches the overlying tissue, which will again increase in area secondary to creep-related mechanisms. Even more rarely used than serial excision, expansion mandates two procedures, multiple clinic visits, and carries risks of infection and implant extrusion. Indications are similar to those for serial excision.

Grafts

Grafts are rarely used in scar camouflage but do exist as an option for large defects not amenable to complete closure. The most common examples of grafts used in this setting are skin grafts (split-thickness, full-thickness, or dermal) or composite grafts (full-thickness skin with perichondrium with or without cartilage) (8). Important factors to consider if choosing a graft for camouflage purposes are anticipated degree of contracture at the recipient site, placement of the graft with regard to facial subunits and RSTLs, adequacy of blood supply of the recipient bed, resultant scar at the donor site, graft color, and skin thickness similarity to the surrounding normal tissue.

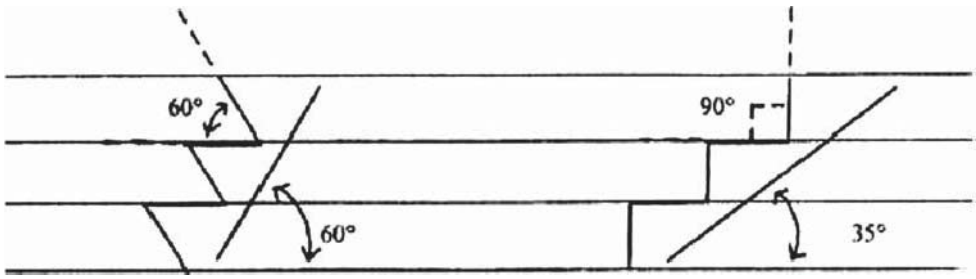

Figure 176.7 Schematic illustrating how the angle between the long axis of the scar and the RSTLs helps to predict the angles that the W-plasty limbs should be designed, in order to improve the alignment of the final incisions with the RSTLs. (From Rodgers BJ, Williams EF, Hove CR. W-plasty and geometric broken line closure. *Facial Plast Surg* 2001;17(4):239–244, Figure 2, p. 240.)

Figure 176.8 Patient with an atrophic widened scar that transgresses multiple aesthetic subunits. Serial revision was planned. Starting with repairing the lower half of the scar on the cheek. Geometric broken line closure technique was performed. **A:** Preoperative photo of the cheek portion of the scar. **B:** Intraoperative design of the GBLC. **C:** One week postoperative photo of GBLC with plans to remove sutures. **D:** Three months postoperative photo. The scar is no longer depressed and has improved width, and the irregularization makes the scar less noticeable.

Concepts in Prevention and Surgical Technique

To achieve an optimal aesthetic result after any intervention, careful surgical planning for incision placement and tissue transfer is paramount. Proper tissue handling techniques are also of critical importance and include atraumatic tissue manipulation, aseptic technique, and meticulous hemostasis (3,14,15). Careful placement of deep dermal sutures to achieve maximal wound eversion should be executed to prevent atrophic scar formation. Also of importance are the location of incisions with respect to

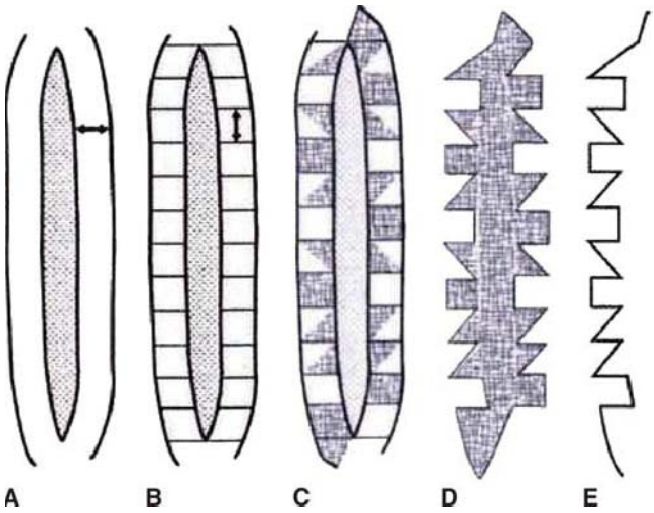

Figure 176.9 Description of the technique used to design geometric broken line advancement flaps. **A:** Lines are drawn parallel to the borders of the scar and are 5 mm beyond the borders of the scar. **B:** Horizontal lines are drawn 5 mm apart between the scar edge and the outer vertical lines. **C:** Shaded area represents the proposed excision of the geometric shapes. Each side must mirror the geometric shapes to allow for advancement of the incisions. **D:** Defect following excision of the scar. **E:** Resulting geometric line following closure. (From Shockley WW. Scar revision techniques. *Oper Tech Otolaryngol* 2011;22:84–93, Figure 11, p. 91.)

hair follicles (risk for alopecia) and proper postoperative nutrition (3). The proper timing for scar revision is variable, but most surgeons will allow a scar to mature for 6 to 12 months before considering an intervention. However, if the scar is causing significant deformity or dysfunction, earlier intervention is acceptable.

Sound postoperative wound care is also a top priority and should be tailored to the interventions performed. Proper bandaging, maintaining a moist wound environment, and early removal (if possible) of foreign surgical material all portend to superior aesthetic outcomes. Pressure dressings, intralesional injections, and topical therapies, when used correctly, can also lead to better overall cosmesis and may limit future scar formation (2,4). Investigations are showing the use of lasers immediately after primary closure may also achieve improved scar prevention (16,17). Finally, the importance of thorough patient education and avoidance of sun exposure should not be overlooked.

NONSURGICAL AND ADJUNCTIVE TECHNIQUES

While surgery is the mainstay of scar camouflage, a number of adjunctive nonsurgical interventions also exist that can augment and often improve the cosmetic outcome of a surgical intervention. These techniques can also be utilized as monotherapies in the correct settings. This section presents discussions of the various nonsurgical modalities.

Intralesional Injections

Steroids

Steroids continue to be a mainstay in scar camouflage and revision. The mechanism of action is believed to lay in suppression of inflammation and mitosis, while an increase in vasoconstriction has also been described. Corticosteroids injected intralesionally have been shown to be effective in decreasing the elevation and erythema of scars, both as a prevention tactic immediately after surgical closure and as a primary intervention. Steroids also represent a first-line agent in both the prevention and treatment of Hsc and keloids. The agent of choice is usually triamcinolone acetonide (Kenalog). Steroid injections have been shown to flatten 50% to 100% of small keloids, with a 9% to 50% rate of recurrence. These rates improve when the intralesional injection is coupled with other modalities such as silicone sheeting, cryotherapy, and/or surgical excision. Earlier injected wounds also tend to have the best outcomes in terms of scar prevention. Side effects include pain on injection, hypopigmentation, telangiectasias, atrophy, ulceration, and in rare occurrences tissue necrosis. Topical EMLA ointment or lidocaine mixed with the steroid can be used to lessen pain (4,18,19).

Agents under Investigation

A number of additional injectable agents continue to be under investigation for use in scar prevention. These include 5-fluorouracil, bleomycin, verapamil, and interferon alfa-2A among others. These agents have been shown to have limited success on scar elevation, pruritus, and erythema, especially when used to treat Hsc and keloids. All have failed to achieve the wide spread acceptance of steroids; this is likely secondary to significant side effects and theoretical risks if not administered correctly (2,4,18–26).

Resurfacing Techniques

Laser Resurfacing

The use of lasers in scar camouflage and treatment has been and remains a burgeoning area of study in recent years. Lasers can be used as monotherapy or as an adjunct to surgical intervention and other camouflaging procedures (1). Laser therapy is classified as either ablative or nonablative based on the absorption spectrum of the wavelength emitted and depth of penetration. Both classes of lasers play specific roles in scar revision and camouflage.

Ablative Resurfacing Lasers (ARL)

The most commonly used ablative lasers are the pulsed CO_2 laser and erbium: yttrium–aluminum–garnet laser (Er:YAG). The wavelengths of these lasers are primarily absorbed by intracellular water, causing an increase in thermal energy that will eventually precipitate vaporization. Pulsed CO_2 lasers are less selective in their affinity and create a high degree of contiguous thermal necrosis

unless fractionated. This in turn leads to wound debulking, contraction, and stimulation of collagen remodeling. A number of studies have shown ARL to be helpful in the treatment of Hsc and keloids as a monotherapy, and improved results are often realized when used in combination with intralesional steroid injection. Er:YAG causes a lesser degree of tissue necrosis than CO_2 lasers and may better target scar margins.

Disadvantages of ablative lasers include pain, prolonged downtime, persistent erythema (described up to 3 months), hyperpigmentation, hypopigmentation, and increased risk for viral and bacterial infections. Er:YAG exhibits these effects to a lesser degree, thanks to its higher affinity for water and ability to be applied more precisely. Lesser downtimes are also described when compared to CO_2 lasers. Similarly, introduction of fractionated CO_2 laser treatments have aided in decreasing the risk profile and recovery downtime when compared to traditional CO_2 lasers.

Nonablative Resurfacing Lasers (NAR)

Common lasers in this category are the 585-nm pulsed dye laser (585nm-PDL) and neodymium: yttrium–aluminum–garnet laser (Nd:YAG) among others. These lasers work on the principle of selective photothermolysis. The emitted wavelength is absorbed primarily by oxyhemoglobin (chromophores) in the microvasculature, which leads to highly selective vaporization and subsequent tissue ischemia. Intracellular water is largely spared so the tissue necrotizing effect of ablative lasers is not observed. The end effect is a reduction in scar erythema, pruritus, and an overall leveling of the scar surface texture. Studies also show a desirable stimulatory effect on cell signaling that can increase organized collagen deposition and ECM production. Thus, nonablative lasers achieve success in the treatment of atrophic and depressed acne scars, especially when the beam is dispersed into multiple microscopic "subbeams" and the overall treatment fractionated over a series of interventions. Finally, lasers in this class can be used to treat hyperpigmented scars (1,18,27–30).

Disadvantages again include downtime, tissue erythema, pain, and infection risk, although all of these bear much less impact when compared with ablative lasers. Also of note, multiple therapies are often indicated to realize maximal outcomes with NAR. Additionally, all lasers should be used cautiously with Fitzpatrick skin types IV to VI, due to increased complication risks.

Dermabrasion

The concept behind dermabrasion is to level the skin while simultaneously promoting reepithelialization and new collagen production. This technique is typically used in the revision of acne scarring, facial rhytids, and rhinophyma, but can also be used as an adjunctive technique after surgery to smooth uneven scars (Fig. 176.10). The goal of dermabrasion is to injure the epithelium to a predetermined depth. Care is taken to extend only into the papillary dermis, with purposeful preservation of the deeper adnexal structures found in the reticular dermis. These serve as a later source of reepithelialization and migration across the abraded surface area. To determine proper depth, the surgeon must look for the appearance of punctate bleeding characteristic of the papillary dermis. Dermabrasion is performed with a high-speed diamond fraise or wire brush, and strokes must be oriented perpendicular to the direction of wheel rotation to prevent loss of control and allow for even resurfacing (Fig. 176.11). This procedure can be performed under local regional anesthesia in an office setting.

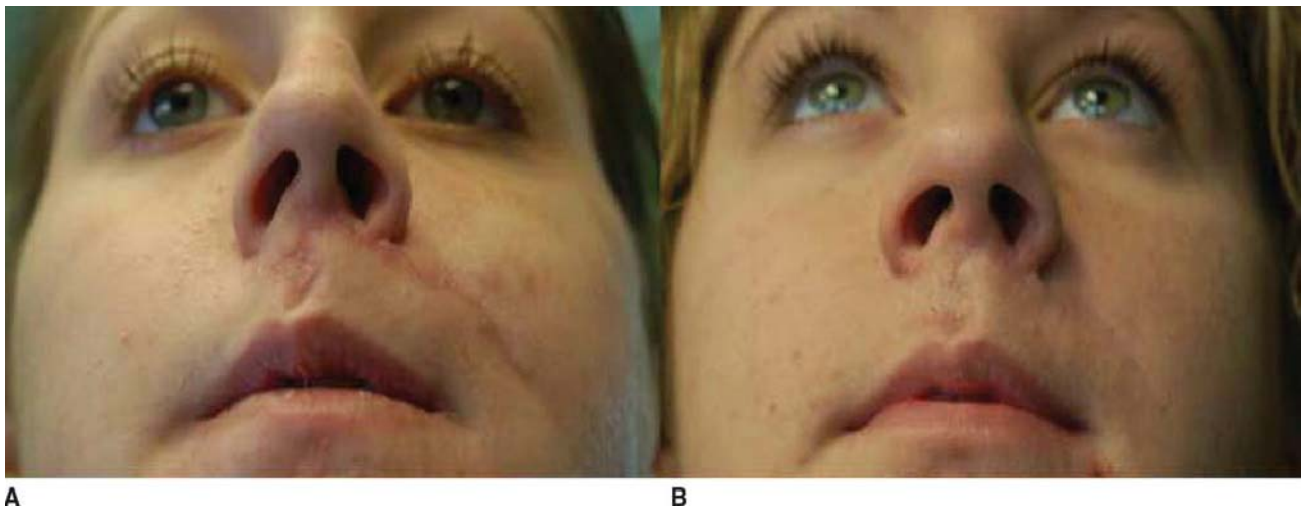

Figure 176.10 Photograph of dermabrasion performed on patient who sustained a severe laceration to the nose and upper lip/cheek. **A:** Preoperative photo 3 months after original injury and just prior to dermabrasion procedure. **B:** Three months after dermabrasion was performed to the upper lip/philtrum/cheek regions. The scar is less conspicuous secondary to the improved smoothness of edges and color match after dermabrasion.

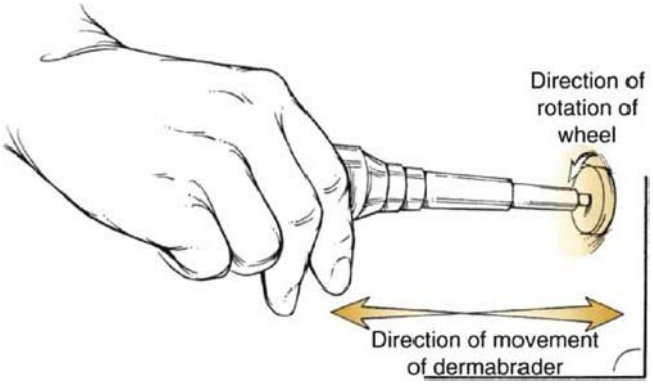

Figure 176.11 Schematic illustrating the technique of dermabrasion. The direction of movement of the dermabrasion should be perpendicular to the rotation of the dermabrader tip. (From Thomas JR, Mobley SR. Scar revision and camouflage. In: Thomas JR, ed. *Cummings otolaryngology head and neck surgery*, 5th ed., Vol. I, Chapter 21, Figure 21–13. China: Mosby Elsevier, 2010:300.)

Cryosurgery/Cryotherapy

This modality entails the use of nitrous oxide and/or liquid nitrogen to damage both cells and microvasculature contained within the scar tissue. This in turn leads to relative vascular stasis, cell anoxia, and necrosis. The clinical affect described is usually a flattening of scar elevation and softening of the scar fibrotic matrix. The latter effect also may assist a surgeon hoping to soften dense scar tissue prior to an intralesional injection or partial excision. Used as a monotherapy, satisfactory improvement has been described in the treatment of keloid and Hsc when used over multiple sessions. In a related technique, cryoneedle probes may also be inserted intralesionally to achieve scar volume reduction (31). Side effects of cryotherapy include tissue edema, atrophy, and risk for hyperpigmentation or hypopigmentation. The latter two are of special concern in patients with darker pigmented skin types (2–4,32,33).

Direct Camouflage

Intralesional Fillers

Injectable soft tissue fillers are also well known and important in the treatment of atrophic scars (34). Types of available fillers include autologous tissue (fat), allogeneic tissue, xenographic materials, and synthetic materials. Caution must be used when injecting permanent filler products in the superficial layers of the dermis and subcutaneous tissues because this may elicit an inflammatory response leading to superficial skin changes and granuloma formation. Such secondary complications may negate the original goal of scar camouflage.

Surgical Tattooing (Dermatography)

Surgical tattooing is a sometimes overlooked modality for the camouflage of aesthetically displeasing scars and can be especially useful in hypopigmented scars and scars involving areas of alopecia (i.e., over the eyebrow). Used in adjunct with other procedures, an improved overall outcome can usually be achieved. Risks are generally limited to pain and slight risk of infection (35).

Topical Cosmetics

Having gained widespread acceptance in the general public, use of cosmetics is logical and effective in certain camouflage scenarios. Best outcomes may be realized when used on hypo- or hyperpigmented scars to blend color tone to surrounding skin. Cosmetics can also be partially successful in leveling atrophic scars and the depressions left by severe acne.

Topical Agents

Moist Wound Dressings

Key in postoperative wound care, a moist wound environment has repeatedly been shown to improve wound healing and overall aesthetic outcomes. It is thought that maintaining a moist environment assists in keratinocyte and epithelial migration from adnexal structures and the epidermal margins of the wound. Dressings of this type can be achieved in a number of ways, but dressings impregnated with Vaseline or petroleum-based products are probably the most practical and cost-effective.

Silicone (Gels, Sheets)

A variety of silicone-based products exist on the market for scar treatment and camouflage including sheets, strips, gels, sprays, and foams. Of these, silicone impregnated elastic sheeting is probably the most extensively studied and has been shown to achieve variable levels of success. The proposed mechanism is occlusion of the wound, which increases temperature, keratinocyte hydration, and oxygen tension inside the forming scar. This in turn seems to lead to the scar softening and flattening. In concept, this is very similar to the mechanism of action of a pressure dressing. The best studied effects have been in the treatment/prevention of Hsc and keloids. One review also shows silicone to have increased efficacy when used in combination with other modalities such as intralesional steroid injections and surgical excision. Side effects are limited, but this agent should be avoided on open wounds and can be expensive. It also requires a very motivated, compliant patient, as the elastomer sheets must remain occlusive for at least 12 hours daily and for prolonged periods of up to 4 to 6 months to be effective (2,4,36,37).

Vitamin E

A popular agent in the treatment of acute and chronic dermal wounds, the effect of vitamin E is thought to be mediated by its antioxidant effects. The desired effect is to reduce wound inflammation and thus limit excessive scar tissue formation during the proliferative and remodeling

phases. Research supporting efficacy of topical vitamin E, however, is relatively scant considering its popularity and has shown it to be no more effective in reduction of scar elevation, color, or appearance than other topical emollients. One important side effect is that vitamin E may reduce the tensile strength of a scar, which should be kept in consideration when planning for high-tension closures (3,4,38). Additionally, unacceptably high levels of contact dermatitis have been reported with vitamin E use.

Onion Extract (Mederma)

This is a very popular agent that has come under recent scrutiny. The active ingredient of this compound is Allium cepa, an onion extract whose derivative is a bioflavonoid called quercetin. Marketed as Mederma, this compound has demonstrated antiproliferative, antiinflammatory, and antihistaminergic effects thought to be effective in decreasing wound erythema, elevation, and pruritus. However, multiple studies have now demonstrated no statistically significant improvements regarding these parameters when compared with simple petroleum-based ointments (3,39). Similar to vitamin E topicals, contact dermatitis is a potential adverse effect.

Imiquimod 5% Cream

Part of a class of drugs called imidazoquinolines, this agent has been thought to work through immune response modulation by inducing production of a number of cytokines such as IFN alfa, IFN gamma, TNF alfa, and a number of interleukins. IFN alfa and gamma, in turn, have been shown to inhibit fibroblast collagen production in a dose-dependent fashion. Imiquimod has best been studied in the treatment and prevention of keloids and Hsc. It is applied postsurgically on alternate nights for 8 weeks and shows best results in low skin tension areas. One area of particular success is use on earlobes after surgical excision of keloids. Side effects include topical irritation and hyperpigmentation (2,4,40).

Other Interventions

Additional modalities described in less detail, or with less orientation to scar treatment and camouflage, include topical retinoids (tretinoin), tacrolimus, cyclosporin A, and mitomycin C. These agents have produced mixed results at best and portend to side effects such as photosensitivity, irritant contact dermatitis, hypertrichosis (cyclosporine), and skin atrophy.

Pressure Dressings

The utility of pressure dressings should not be overlooked. In concept similar to silicone dressings, mechanism is thought to be through occlusion of the wound. Studies have shown that pressure dressings are especially effective for preventing the recurrence of keloids and Hsc after excision.

HIGHLIGHTS

- Characteristics of an ideal scar include the following: thin width, surface is flush with surrounding skin, color matches surrounding skin, and the axis of the scar runs parallel with RSTLs or along aesthetic subunits.
- Transposition (Z-plasty) and advancement (W-plasty and GBLC) flaps are the most common types of local flap techniques employed for scar camouflage.
- Goals of Z-plasty include the following: to lengthen a scar, to release a contracture, to disrupt a scar, or to realign a scar within an RSTL.
- Although a thin scar is ideal, if long and straight, it may continue to be conspicuous and require irregularization.
- GBLC is the superior technique for irregularizing long and straight scars but is technically more challenging and time consuming when compared to Z-plasty and W-plasty techniques.
- Corticosteroids injected intralesionally have been shown to be effective in decreasing the elevation and erythema of scars, both as a prevention tactic immediately after surgical closure and as a primary intervention.
- Popular resurfacing techniques utilized for scar camouflage include dermabrasion, laser therapy, and cryotherapy.
- Resurfacing techniques extend to the depth of the papillary dermis and must preserve the deeper adnexal structures for proper wound healing and reepithelialization.
- Wounds epithelialize most quickly in a moist environment.
- Importance of thorough patient education on wound care and avoidance of sun exposure should not be underestimated.

Nasal Reconstruction

177

Stephen S. Park

Nasal reconstruction has evolved significantly from early, rudimentary attempts to provide covering for large nasal defects. In contemporary nasal reconstruction, surgeons combine a mastery of aesthetics and surgical techniques, to create a nose that is visually inconspicuous and functionally stable. This is expected to hold up throughout the life of the patient. Ancient methods focused on using soft tissue to fill the cavity, with little regard for structural framework, internal lining, intranasal airspace, and intrinsic contours. Nasal reconstruction in the 21st century has raised the bar to a level where the new nose may go unnoticed by the casual observer, nasal function returns to the baseline, and the patient integrates back into society without undue self-consciousness.

HISTORY OF NASAL RECONSTRUCTION

The history of nasal reconstruction dates back to antiquity when, during the fourth Egyptian dynasty (2575–2467 BC), prostheses were molded for the deceased, because "only those without physical disfigurement would enter the Kingdom of Osiris" (1). Reconstruction came into greater demand with the rise of nasal mutilation as a common form of humiliation or punishment. Around 1500 BC, when Prince Lakshmana of India deliberately amputated the nose of Lady Surpunakha, King Ravana arranged for the reconstruction of Lady Surpanakha's nose by his physicians, documenting one of the earliest accounts of nasal restoration in human history (2,3). *Sushruta Samhita*, an ancient Indian Sanskrit written during the Vedic period (600–1000 BC), describes nasal reconstruction as performed by a caste of Indian potters, using cheek tissue to cover the nasal defect (4). Early descriptions of using forehead tissue to repair a nasal defect exist in writings by the Kangiara family from 1440 AD (5). Despite the long history with this type of reconstruction, very little international exchange occurred because of the lack of maritime commerce and little communication between Europe and Asia during that period. In the 16th century, Gusparo Tagliacozzi described his success with a two-staged method of nasal reconstruction using a pedicled, cutaneous flap from the upper arm, based on the brachial vessels. This was followed by attempts with pedicled flaps from other individuals, especially slaves. Outcomes were obviously discouraging, and further progression was shortly abandoned.

In 1794, the first description of the Indian forehead flap in the English language was published in the *Madras Gazette* and later reproduced in *Gentleman's Magazine* (6). Joseph Carpue (7), an English general surgeon, is credited with the introduction of this forehead flap to the Western world when he described his experience with two successful "Indian forehead flaps" for nasal reconstruction. Subsequently, the classic forehead flap for nasal reconstruction became widespread throughout the globe and defined the standard method of repair during the early 19th century. This "classic" Indian median forehead flap was based on bilateral supratrochlear arteries with a wide pedicle that could not extend beyond the level of the brows. The wide base limited the rotation and length of the forehead flap. This limitation became more evident when it was recognized that intranasal lining left to heal by second intention resulted in significant distortion, contracture, and nasal obstruction. This restricted design could not be designed to line the intranasal defect.

Pedicled flaps moved slowly to the United States; the first American reports of forehead flaps for nasal reconstructions are from the 1940s (8,9). These early flaps were traditional "median" forehead flaps with wide pedicle bases capturing both supratrochlear vessels. Kazanjian and Converse believed that the paired arteries were needed to adequately perfuse the forehead flap. Because of the limited length of this early median forehead flap, many variations were described, largely aimed at mobilizing more tissue with greater flap length: "Gillies' up-and-down flap" (10), "New's sickle flap" (11), "Converse's scalping

flap" (12), and the "Washio flap" (13). In spite of the variety of flaps attempted, none have stood the test of time primarily because of the poor quality of scalp skin in contrast to forehead skin and the significant donor site morbidity.

Millard repopularized the paramedian flap with a "seagull" design for resurfacing the nose (14–17). The primary advantage of this paramedian flap was the narrow pedicle base, which allowed for an improved arc of rotation. The inferior reach of the flap could be further extended by basing the pedicle below the level of the brow. This design created less narrowing of the brows in contrast to the original "median" forehead flap. Millard also noted that the supratrochlear artery traveled in a plane between the skin and frontalis muscle, and, consequently, the frontalis muscle could be selectively trimmed off the undersurface of the flap without jeopardizing flap vascularity. Gary Burget and Fred Menick (18) have since refined these concepts of the paramedian forehead flap design and have brought nasal reconstruction to its higher standards.

ETIOLOGY OF NASAL DEFECTS

Defects of the nose arise from a large array of causes, and, on many occasions, it is worthwhile to consider the specific etiology as it may impact the method of repair. The nose is the most common site for *de novo* cutaneous malignancies. Basal cell carcinomas predominate, and there are histologic subtypes with varying degrees of aggressiveness. The nodular subtype is most common, as characterized by a circumscribed growth pattern, and carries the most favorable prognosis. Aggressive histologic subtypes, such as the morpheaform or infiltrating, can develop small nest patterns and are more likely to involve the internal lining or to recur following surgical excision. These latter subtypes are best treated with Mohs surgery. Squamous cell carcinoma is the second most common type and also behaves aggressively, with a greater incidence of regional metastasis. Melanoma is the most serious skin tumor, warranting an aggressive surgical intervention. Recurrent skin tumors or tumors that have been previously irradiated have a less predictable vascular anatomy, which may impact flap design and closure options. Vascular and adnexal tumors of the nose are less common but often require more aggressive treatment plans. Sharp and blunt trauma to the nose, such as from motor vehicle accidents, can lead to nasal defects with associated variables for consideration. Animal or human bites are grossly contaminated, and a delay in repair is often advocated. This dogma arises from experience with extremity injuries; however, the face is characterized by such a robust vascularity that immediate repair will often be successful.

NASAL ANATOMY

A firm understanding of the normal nasal anatomy is a prerequisite for mastery of nasal reconstruction. The biomechanics of covering flaps, the importance of a firm framework, and the anatomic basis for internal lining repair are imperative concepts as one proceeds through the algorithm of reparative options.

The *external nasal skin* is variable at different areas of the nose, being thick at the nasion and tip and extremely thin along the rhinion. The thin epithelial sleeve along the alar rim and nasal facets makes these areas especially vulnerable to notching and contour irregularities following reconstruction.

There are four layers of *soft tissue* between the skin and the nasal skeleton—the superficial fatty panniculus, fibromuscular layer, deep fatty layer, and, finally, the periosteum or perichondrium. The superficial fatty panniculus is located immediately below the skin and consists of adipose tissue with interlacing vertical fibrous septi coursing from the deep dermis to the underlying fibromuscular layer. The fibromuscular layer contains the intrinsic nasal musculature and the nasal superficial musculoaponeurotic system (SMAS), which is a continuation of the facial aponeurotic system. The deep fatty layer located between the SMAS and the thin covering of the nasal skeleton contains the major superficial blood vessels and nerves. The periosteum of the nasal bones extends over the upper lateral cartilages and fuses with the periosteum of the piriform process laterally (19). Perichondrium covers the nasal cartilages, and dense fibrous interconnections can be found between the paired tip cartilages. Between the framework and the deep fatty layer is a plane of loose areolar tissue that is free of fibrous septa, making it an ideal plane for dissection and elevation of the soft tissue envelope.

The *nasal musculature* of the nose is well defined, with greatest activity along the junction of the upper lateral and alar cartilages (20). This allows for muscular dilation and stenting of the functionally critical nasal valve area. All nasal musculature is innervated by the zygomatic division of the facial nerve (21).

The nasal *blood supply* is via a predictable and consistent network of named vessels through both the internal and external carotid systems. The angular artery branches from the facial artery and is a discrete landmark along the nasofacial junction. Feeder vessels off the angular artery perforate the levator labii superioris and provide the vascular basis for the design of melolabial flaps. A medial branch off the angular artery, the lateral nasal artery, supplies the lateral surface of the caudal nose. This lateral nasal artery courses in the sulcus between the ala and nasal sidewall and is covered by the levator labii superioris alaeque nasi. It arborizes multiple times to enter the subdermal plexus covering the nostril and cheek and is the anatomic basis for many small local flaps within the lateral nasal wall, for example, bilobe flaps. The dorsal nasal artery, a branch of the ophthalmic artery, pierces the orbital septum above the medial palpebral ligament and travels inferiorly along the side of the nose to anastomose with the lateral nasal artery. The dorsal nasal artery provides a rich axial blood supply to the dorsal nasal skin and serves

as the main arterial contributor to dorsal nasal flaps. The columella and tip are supplied by the paired columellar arteries, branches of the superior labial artery. The external nasal branch of the anterior ethmoidal artery, a branch of the ophthalmic artery, pierces bone on the medial wall of the orbit at the point where the lamina papyracea of the ethmoid bone articulates with the orbital portion of the frontal bone (frontoethmoid suture). The vessel enters the ethmoid sinuses to supply the mucosa and sends branches to the superior aspect of the nasal cavity. The external nasal branch of the anterior ethmoidal artery emerges between the nasal bone and the upper lateral cartilage to supply the skin covering the nasal dorsum and tip. The venous drainage of the external nose is through corresponding vessels, leading into the facial vein, the pterygoid plexus, and the valveless ophthalmic veins.

The *intranasal mucosa* has a similar number of named vessels, and they are critical when designing mucosal flaps for full-thickness nasal defects. The septal branch of the superior labial artery is a dominant feeder to the septal mucosa. In fact, a flap of the entire septal mucosa, back to the sphenoid sinus, can be based on this single vessel. The anterior and posterior ethmoidal vessels supply the superior portion of the septum. Terminal branches of the anterior ethmoidal artery cover the dorsal nasal septum, a critical region for the swinging, composite septal flaps used for internal lining and structure. Terminal branches of the sphenopalatine artery supply the posterior septum and posterior lateral nasal wall. The vasculature of the internal nose is the anatomic basis for complex nasal reconstruction.

The *sensory nerve* to the nasal skin is via the ophthalmic and maxillary divisions of the fifth cranial nerve. Branches of the supratrochlear and infratrochlear nerves supply the skin covering the radix, rhinion, and cephalic portion of the nasal sidewalls. The external nasal branch of the anterior ethmoidal nerve supplies the skin over the caudal half of the nose. The infraorbital nerve provides sensory branches to the skin of the lateral aspect of the nose.

The *structural framework* of the nose is composed of the paired nasal bones to the upper third, the nasal septum and upper lateral cartilages to the middle vault, and the paired lower lateral cartilages within the nasal tip. Dorsal support to the middle vault is primarily achieved through the rigidity of the cartilaginous septum and, to a lesser extent, the paired upper lateral cartilages. Their fusion at the midline is important clinically because of the tendency for the upper lateral cartilages to progressively contract intranasally and lead to obstruction. If a disarticulation between the septum and upper lateral cartilages occurs, the middle vault should be diligently reconstructed.

The tip is supported by the overall size and strength of the lower lateral cartilages, their ligamentous attachments to the caudal septum, the scroll with the upper lateral cartilages, and the adherence to the overlying soft tissue. Each lower lateral cartilage is subdivided into the medial, intermediate, and lateral crura. The shape, length, and angulation of the intermediate crura determine the external morphology of the tip lobule and the position of the tip-defining point. Disruption or weakening of the lateral crus predisposes to alar retraction and notching, an important consideration in nasal reconstruction when these structures may have been compromised. Laterally, small sesamoid cartilages are interconnected by a dense, fibrous connective tissue.

The *alar lobule and nasal sidewall* is a functionally pivotal area of the nose that is not often highlighted during rhinoplasty discussions but has a critical role during reconstructive surgery. This *keystone* region is located between the lateral border of the lower lateral cartilage and the bony piriform aperture. Externally, it corresponds to the supra-alar crease and is the most common location for a clinically significant, dynamic valve collapse. Beneath the skin, the area consists of a firm, fibrous-fatty aponeurosis, an occasional sesamoid cartilage, and a portion of the transverse nasalis muscle. Typically, this histologic architecture provides sufficient rigidity to prevent collapse during inspiration. If compromised, nasal function will be impaired unless it is aggressively restored with liberal grafting in a nonanatomic fashion. The *internal nasal valve* is a distinct area defined by the dorsal septum medially, upper lateral cartilage superolaterally, and the head of the inferior turbinate inferomedially. The *external nasal valve* is the cross-sectional area under the alar lobule proper. It does not entirely correlate with the lateral crus of the lower lateral cartilages. The alar rim does not have cartilage within it, and collapse or notching can readily occur. To avoid this, structural grafts to the alar rim are often needed. The junction between the ala and cheek forms an acute angle and is difficult to reconstruct; most repairs heal with gradual effacement of that alar–facial angle and may become increasingly conspicuous. If at all possible, one should try to preserve the alar–facial junction and keep incisions slightly onto the nose. The *limen vestibuli* is the junction between the internal nasal lining and the stratified squamous epithelium of the nose. It does not lie at the caudalmost border of the alar lobule but rather slightly intranasally, within the vestibule. Reconstruction of full-thickness defects of the alar rim should keep this in mind and allow the resurfacing flap to roll inward before suturing to the internal lining flap.

There is a *bony piriform platform* that surrounds the nose, and its role in tissue support is often poorly appreciated. The nasal sill, anterior nasal spine, and medial maxilla (including the frontal process of the maxilla) provide an essential platform for the nose, and resection of these structures will require a separate repair, such as with a split calvarial bone graft. Failure to rebuild this platform will often result in a soft tissue collapse and facial asymmetry.

DEFECT ANALYSIS

Analyzing a given defect and arriving at the ideal method of repair is a challenging and rewarding exercise. On occasion, the "correct" flap will be intuitive, as it appears to

define itself. At other times, it can be a creative dilemma as one struggles to visualize the incisions, flap transfer, surrounding vectors of tension, and final scars. This mental challenge requires a dynamic, three-dimensional image of the nasal repair. At times, it is worthwhile to have a structured algorithm for defect analysis. Although it does not necessarily define the ideal flap, it can be very useful in avoiding errors in design. In particular, the line of questioning can guide one away from creating disfiguring mistakes such as eyelid retraction or an unnatural hairline. Once flaps are elevated and transposition is attempted, the reconstruction is committed; this is clearly not the time to discover a gross design flaw.

For every cutaneous defect, there are six questions that are reviewed prior to the first incision (Table 177.1):

1. *Immobile structures*. What surrounding landmarks must not come under any tension during flap transposition, such as the eyelid, alar margin, or upper lip? It does not necessarily mean that tissue cannot be recruited from that region but rather, adequate structure must be available in the area to fully support the adjacent flap. A common example is a cheek flap that risks lower-eyelid retraction and is vertically supported with anchors to the infraorbital rim. For the nose, there are three "immobile structures": the alar rim, nasal base symmetry, and lateral nasal wall. The immobility of the lateral nasal wall is a unique concept. Most flaps are thought of in two dimensions. The nose, as a three-dimensional structure, has an important lumen. The additional vector of tension is in this third dimension, perpendicular to the cutaneous plane. Local flaps tend to create a force perpendicular to the plane of rotation, leading to sidewall collapse and functional compromise. Recognition of this concept allows one to plan the reconstruction with prophylactic support grafts.
2. *Area of recruitment*. Given which surrounding areas are "immobile," from where can tissue be recruited without distorting those areas? Also, in what direction do the lines of maximal extensibility exist and how can the flap be designed to slide parallel with them?
3. *Facial lines*. There are numerous descriptions of facial lines that can assist with flap selection and design. Langer lines were first described by Langer (19) in 1861 as a recommendation for orienting elliptical skin excisions. Circular defects in postmortem patients became elliptical as rigor mortis ensued, and these lines were mapped throughout the body. Clinical practice has shown that these lines do not always orient along lines for optimal healing. Relaxed skin tension lines (RSTLs) more accurately reflect the intrinsic tension within the dermis while at rest. Wounds heal under less tension when oriented along them, and they can usually assist with flap design. Lines of minimal tension (also known as skin creases) are defined by the repeated contraction of the underlying muscle as they permanently orient elastin and collagen fibers within the dermis. These lines usually run parallel with the RSTLs, but the supratip, glabella, and lateral canthal regions are in conflict. It is usually recommended to incise along lines of minimal tension rather than RSTLs.

TABLE 177.1 DEFECT ANALYSIS

1. Immobile structures
2. Area of recruitment
3. Facial lines
4. Resultant scars
5. Nasal function
6. Depth

The other "facial lines" that exist in the face are those created by the borders of *aesthetic units* and the subunits of the nose. The principle of aesthetic units is based on the fact that the human eye can only perceive things as a series of block images, thus our inability to scan a horizon without a saccadic motion. The face, or nose, is visualized as a discrete set of block images that are put together subconsciously and interpreted as a single image. These images are defined by predictable reflections of light, natural creases, and undulations in cutaneous topography. The nose has subunits defined as the nasal tip, dorsum, columella,

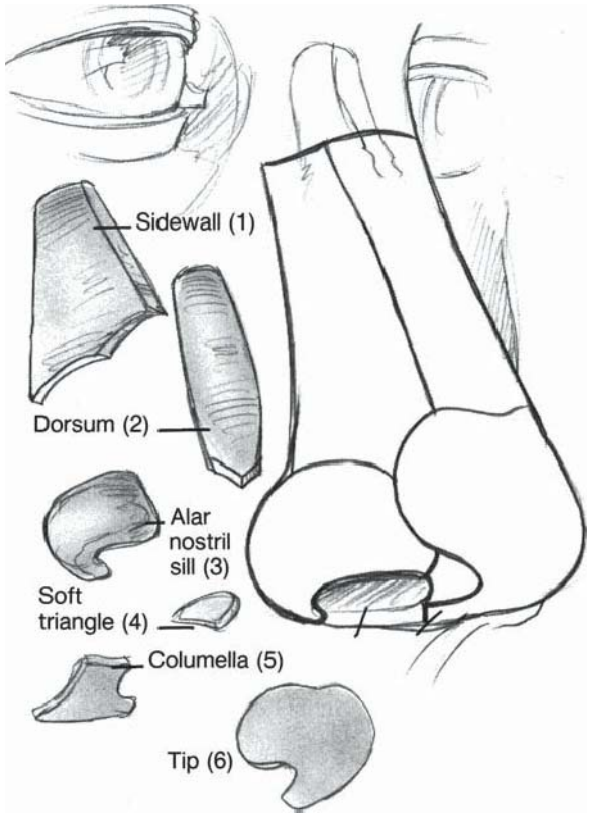

Figure 177.1 Nasal aesthetic subunits.

paired ala, sidewalls, and soft tissue facets (Fig. 177.1). Scars that are strategically placed at the border of two units will be less conspicuous than those resting within one. In order to achieve this, one usually has to modify the size/shape of the original cutaneous defect. The aesthetic subunits may require modifications with some patient groups who have other unique nasal characteristics. At times, a patient may have a significant transition from one skin type to another within the nose, such as individuals with rosacea or a rhinophyma (20).

4. *Resultant scars*. One should anticipate the final scars for each proposed flap and how they relate to preexisting facial lines. At times, this exercise is not intuitive, such as the resultant scars of a rhombic flap. This question forces the surgeon to try different orientations of flap design that might yield more favorable scars while still abiding by the previous tenets of immobile structures and area of recruitment.
5. *Function*. During the defect analysis, one of the essential considerations is the *location* in terms of function and potential lateral wall collapse. A cutaneous defect involving the critical area along the supra-alar crease will place the nasal airway at jeopardy even if the original defect does not violate native cartilage. This critical "red zone" must alert the reconstructive surgeon of the need for structural reinforcement in the form of cartilage grafting. Anatomically, it corresponds to the fibroareolar tissue immediately lateral to the lateral crus of the lower lateral cartilage and is distinct from the precise *internal* and *external nasal valves*. Similarly sized defects along the dorsum or upper third do not have the associated functional concerns.
6. *Depth*. Assessing the depth of the nasal defect is important to determine if any structural cartilage or bone is missing and to explore the internal nasal lining. Any violation of the intranasal mucosa must be recognized preoperatively, as it will alter the reconstructive plan significantly; all missing lining must be meticulously repaired prior to grafting and resurfacing. Failure to do so will risk contracture, lumen stenosis, graft exposure and resorption, and alar notching.

SMALL CUTANEOUS DEFECTS

Cutaneous defects of the nose can be found in a variety of sizes, depths, and shapes. Intuitively, the smaller ones should be more straightforward in terms of repair, but that is often not the case. Whereas large defects have a limited number of options, those less than 1.5 cm can be repaired with an array of flaps and grafts, often creating a greater intellectual challenge. Furthermore, patient expectations are generally higher with small lesions, and even small irregularities that often plague these repairs can be problematic, such as alar base asymmetry, notching, conspicuous scars, pincushioning, or valve collapse.

Pertinent Anatomy

Nasal topography during reconstruction is often discussed in terms of aesthetic subunits, but since smaller defects frequently involve only small portions of an individual site, it is more practical to discuss the defect in terms of the upper, middle, and lower thirds of the nose. The *upper third* has relatively thin skin except for the nasion region, where the subcutaneous tissue is much more prominent. The lateral borders are adjacent to the medial canthus and represent *immobile* regions that cannot be distorted, especially from contracture during second-intention healing. The area of recruitment is primarily from the glabella and, to a lesser extent, from the nasal dorsum. There is little functional concern with defects in this zone.

The *middle third* of the nose has skin that is thin medially but thicker laterally. Whereas the upper lateral cartilages support the medial portion of this zone, the lateral aspect has support only from fibroareolar tissue without native cartilage. Tissue can be recruited from multiple directions, but any vertical vector must be minimal, as ala or tip elevation can quickly occur. Functional implications are important along the lateral aspect of the middle vault, even if no native cartilage has been violated. The lateral nasal artery is found immediately cephalad to the supra-alar crease and is the basis for many local flaps of the nose.

The *lower third* of the nose consists of the nasal tip, alar lobule, columella, and soft tissue triangle. The skin is typically thicker and more sebaceous, leading to less favorable wound healing. Most defects of this region are repaired with tissue recruited from the middle vault, but great care must go into flap design and the subsequent vectors of tension. This zone is significant for its free alar margin and the fact that small degrees of wound contracture may lead to retraction and gross alar base asymmetries. The supra-alar crease and alar–facial junction are important natural landmarks that should be preserved or recreated. The alar lobule proper does not contain native cartilage, and disruption to this area predisposes to a dynamic external nasal valve collapse. Consequently, nonanatomic cartilage grafting is essential to prevent alar rim retraction and collapse.

SELECTION OF GRAFTS AND FLAPS

At times, the simplest method of repair is also the preferred one in terms of optimal aesthetic results. Second-intention healing, skin and composite grafts, and local flaps all enter the algorithm for repair of such defects, and proper selection becomes the cornerstone for a successful outcome (Table 177.2) (21). Individuals with a large nose, prominent hump, or broad nasal tip can have their nose reduced slightly, and it will not only create more tissue for recruitment but also reduce the relative size of the defect. The use of common aesthetic rhinoplasty maneuvers in the setting of nasal reconstruction can be a powerful tool. Hump reduction, cephalic trim, tip sutures, etc., all can have great

TABLE 177.2 COMMON RECONSTRUCTIVE OPTIONS FOR SMALL CUTANEOUS DEFECTS

Upper 1/3	1. Local transposition flaps 2. Full-thickness skin graft 3. Second intention
Middle 1/3	1. Primary closure (midline or paramedian) 2. Full-thickness skin graft (in combination with #1 above) 3. Bilobe transposition flap 4. Single-stage forehead flap
Lower 1/3	1. Primary closure (midline, broad tip; with/without FTSG) 2. Bilobe transposition flap 3. Composite graft (alar rim, columella) 4. Interpolated melolabial flap (ala, columella; with cartilage graft)

utility with medium size nasal defects. For many defects, this maneuver can allow the transition from a more complex repair to a simpler one with local flaps or grafts.

Upper Third

Smaller defects in this zone are readily repaired with either a full-thickness skin graft or by second-intention healing. Those larger than 1.5 cm can be resurfaced with a sliding glabellar or Rieger flap (22). Other transposition flaps recruited from the forehead and middle third of the nose are less common alternatives.

Middle Third

Small midline defects are often amenable to primary closure with wide undermining and recruitment from lateral nasal tissue; this often represents the first option for optimal repair. It will leave a vertically oriented central scar with tension evenly distributed, thus maintaining nasal symmetry. Many times, a medium-sized defect in the midline can be converted to a small defect with partial closure through bilateral advancement flaps, leaving a residual defect in the midline. The remainder can be resurfaced with a full-thickness skin graft, harvested from the standing cutaneous deformities of the primary closure. This skin is ideally suited for this because of the excellent color/texture match and lack of donor site morbidity. Small transposition flaps (rhombic, bilobe, rotation) are frequently utilized and represent another workhorse repair for this region. Skin grafts can blend in well with the thin skin of this zone, but even small contour depressions are difficult to disguise, as their shadows often remain conspicuous. If a cartilage graft is needed along the lateral wall, a vascularized resurfacing flap is needed. Those larger than 1.5 cm often require a more elaborate flap.

Lower Third

Precise midline defects are ideally suited for primary closure, particularly when the premorbid nasal tip is somewhat bulbous and can afford to be narrowed. Like the middle vault, partial closure with skin grafting from the standing cutaneous deformity is a useful technique. A bilobe flap is often utilized for defects of the nasal tip, allowing the tension to be distributed more widely and at an adequate distance from the free alar margin. The alar lobule is often repaired with composite grafts, restoring structure and covering simultaneously. Smaller defects limited to the supra-alar crease can do well through second-intention healing, but moderately sized defects will jeopardize nasal patency. The single-stage melolabial flap can also be used; however, the supra-alar crease is often obliterated and asymmetry can result if the contralateral supra-alar crease is deep and prominent. A two-stage, interpolated melolabial flap is preferable for larger defects of the alar lobule, especially when cartilage grafts have been placed and the aesthetic unit completed. Small, full-thickness defects involving the alar margin are best repaired with a three-layered composite graft from the ear, whereas larger ones require a multilayered reconstruction involving the internal lining, structural framework, and resurfacing. The columella is characterized by a very narrow column of thin skin and lends itself well to small composite and skin grafts. For larger columellar defects, structural grafting along with a pedicled melolabial flap is most often used. The soft tissue triangle defect is ideally restored by allowing second-intention healing to occur with a natural-appearing web.

TECHNIQUES FOR GRAFTS AND FLAPS

Second-Intention Healing

Local wound care is the most important aspect when selecting this method of repair. Keeping the wound bed moist and preventing the development of a dry eschar will encourage the most prompt and favorable healing. Cytotoxic agents, especially hydrogen peroxide, should be avoided. A *guiding suture* can be employed in a similar fashion to the purse-string closures used for large defects on the scalp and face. This guiding suture partially closes a small defect and allows the remainder to heal secondarily. The greatest utility of this suture is for small defects along the alar rim. The suture can be placed horizontally, thus converting the circular defect into a vertical elliptical shape, which resists the vertical contracture that will ensue. The suture itself will often notch the alar rim inferiorly slightly, but it contracts to a normal position during healing. The suture is removed after 2 to 3 weeks. This technique will allow more defects to be managed in a conservative fashion.

Skin and Composite Grafts

Superficial defects can be immediately repaired with full-thickness skin grafts and perform well (Table 177.3). For deeper defects, or those exposing bare cartilage, it may be prudent to delay the repair for 10 days allowing a layer of granulation tissue to accumulate within the recipient bed. This enhances vascularity and fills in the depression, thereby improving surface contour. The defect shape is modified, in order to create straight lines with square corners, rather than leaving a circular defect. The entire aesthetic subunit is not necessarily completed. Wound margins are beveled toward the center of the defect in order to smooth the transition between graft and the native nasal skin. Skin grafts can be harvested from the supraclavicular fossa, periauricular skin, and melolabial area. Graft thickness is modified following harvest to best match the surrounding skin texture, especially along the nasal tip, where thicker skin is found. Small "pie crusts" can be cut into the graft to allow the egress of serous fluid, recognizing that these perforations often become discolored and remain noticeable. A bolster dressing is rarely needed on the nose as long as small tacking sutures are placed to maintain close apposition between the graft and recipient bed.

A two- or three-layered composite graft is usually taken from the ear—either the root of the helix, the conchal bowl, or the triangular fossa. Anterior auricular skin is tightly adhered to auricular cartilage and has a good success rate. The shape of the cartilage is usually concave toward the skin, and although this shape can be unfavorable for external resurfacing, it is ideal for internal lining. The auricular donor site is closed primarily with little distortion. Excising cartilage from the apices of the donor site can avoid the "cookie bite" deformity to the ear. The composite graft must be securely attached to the nose, often with through-and-through sutures or a small bolster. These grafts are ideally suited for defects along the alar rim and columella (Fig. 177.2). Many composite grafts will appear moderately dusky for a week but will usually recover during the ensuing days. Larger grafts may undergo a degree of epidermolysis, which will lead to a less favorable color and texture match. Three-layered composite grafts are kept less than 1.5 cm because the sole blood supply is from the peripheral margin. Two-layered composite grafts, on the other hand, can be designed larger because the nourishing bed is the entire surface area of the graft. When utilizing these larger, two-layered composite grafts, one can excise several small, 2-mm punch holes through the cartilage only, taking care not to puncture the overlying skin. These small perforations will allow granulation tissue to penetrate the cartilage and nourish the epithelial covering.

TABLE 177.3 PEARLS FOR SKIN AND COMPOSITE GRAFTS

4. Minimize "pie crusts."
5. Small perforations through cartilage for larger composite grafts can help.
6. No dead space—consider a bolster or tacking sutures.

Primary Closure

Primary closure with wide undermining is an excellent option for many small cutaneous nasal defects, especially those located in the precise midline of the lower two-thirds of the nose and when the tip is modestly wide or bulbous to begin with. Lateral undermining over the perichondrium, and deep to the nasal SMAS layer, is essential. The elliptical design requires that the vertical apices extend further superiorly and inferiorly than the traditional 30-degree angles, in order to avoid an asymmetric narrowing of the nose. Failure to do so will narrow the nose at the site of the original defect while leaving the supratip or infratip segments disproportionately wide. Common rhinoplasty maneuvers, such as an interdomal suture and cephalic trim, are frequently utilized concomitantly in order to narrow the tip, reduce wound tension, and facilitate primary closure. These bilateral advancement flaps are very useful for medium-sized defects that are partially closed and convert the defect to a smaller one. The remainder is resurfaced with a full-thickness skin graft from the standing cutaneous deformities of the local flaps (Fig. 177.3A–H).

Defects that are off midline will leave a paramedian vertical scar and may create nasal asymmetry because of uneven recruitment and tension. In those circumstances, an "east–west" flap can be designed to control the resultant scars and move the standing cutaneous deformity to a favorable location in the midline (Fig. 177.4A–D).

Rhombic Flap

The design of the classic Limberg rhombic flap was originally described in 1946 and remains a versatile flap with predictable scars and vectors of tension (23). Because the resultant scar crosses all aesthetic units, it is difficult to orient the flaps such that scars are maximally camouflaged. In order to minimize wound tension, however, flaps are specifically designed such that the vectors of tension parallel those lines of maximal tissue recruitment. In the nose, this laxity is usually from the lateral nasal wall and medial cheek. In addition, an inferiorly based flap tends to have fewer problems with postoperative congestion and edema.

Bilobe Flap

The bilobe flap is widely used for a small nasal defect because it allows one to distribute tension further from the

primary defect, thus controlling the degree of tension along the alar margin. Whereas early designs utilized a 180-degree arch of rotation, contemporary methods have narrowed this angle in order to minimize the standing cutaneous deformity (24). Common sequelae to these flaps include postoperative edema and "pincushioning," which can arise from several factors: (a) the curvilinear scars of the flap design will undergo natural contraction and, as they shorten, tend to bunch and lift the skin paddle of the flap; (b) a bilobe is relatively wide with respect to its pedicle, predisposing to congestion; and (c) a plane of scar tissue will form beneath the flap and further impede lymphatic egress. In an attempt to minimize these effects, certain modifications of the bilobe can be employed. By decreasing the arc of rotation to 90 degrees, the size of the standing cutaneous deformity and the overall width of the flap are decreased. The primary flap should be aggressively debulked, removing all muscle and a majority of the subcutaneous fat. When possible, an inferiorly based flap design will be more favorable, as it permits lymphatic drainage. The entire nose is widely undermined, creating a more even plane of scar and contracture. Finally, the apex of the secondary flap can be

F

G

H

Figure 177.3 *(Continued)* **F–H**: Six-month postoperative views.

left as a triangle rather than trimming it, leaving a sharp corner that contracts less. This requires a small triangle of normal skin to be excised from the recipient normal nasal skin. Wound edges along a bilobe often become inverted and depressed. Great effort must be made to maximize skin eversion during closure with meticulous subdermal sutures. It is often possible to orient the flap such that one limb of the primary flap and the straight line from the secondary flap closure are indiscreet. One can place the Burrow triangle from the primary flap along the supra-alar crease or orient the secondary flap vertically, such that the closure of this donor site parallels the borders of aesthetic subunits (Fig. 177.5). The vector of tension from a bilobe is often counterintuitive in that there is an inferior force that can push the alar rim inferiorly. The flap border may need to be trimmed in order to pull the rim cephalad. Because of the natural convexity of the nose, the pivot point of a bilobe also has a third-dimensional vector that is perpendicular to the plane of the flap and impinges on the airway. Most bilobes designed with the pedicle based laterally along the keystone area will compromise the valve and will require a prophylactic sidewall batten graft. Those based medially, on the other hand, tend to be more functionally forgiving and may even serve to pull the sidewall open.

Rieger Flap

The Rieger flap utilizes glabellar skin based on a unilateral medial brow/supratrochlear region. The donor site is closed primarily as the glabellar and dorsal nasal skin is advanced and rotated caudally. It is ideally suited for defects of the upper two-thirds. For lower-third defects, it is a moderately large flap that often leaves some alar base asymmetry as well as unnatural nasal creases.

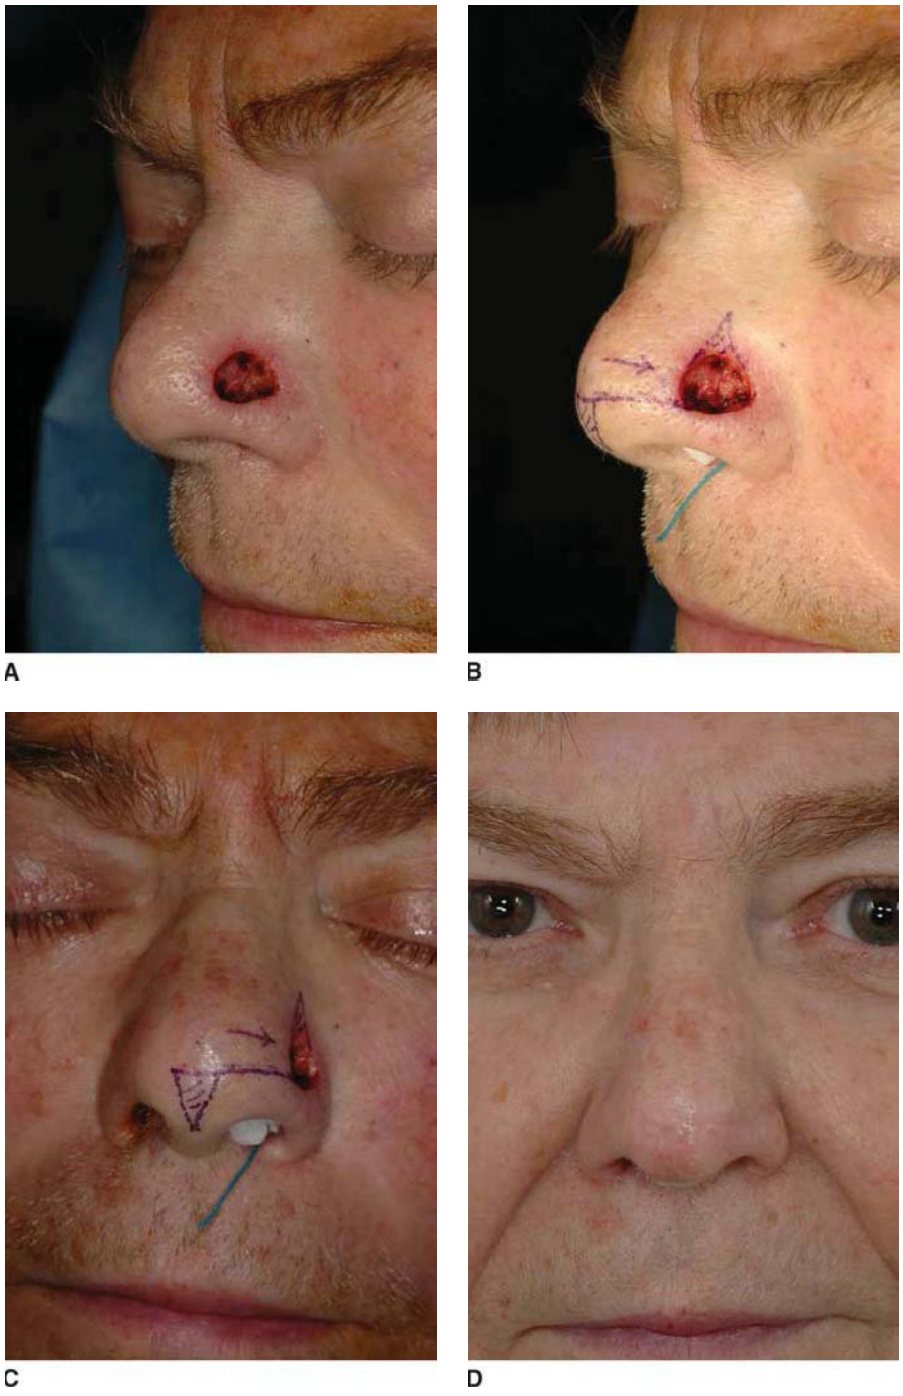

Figure 177.4 East–west flap. **A**: Left sidewall defect. **B, C**: Flap designed with standing cutaneous deformity moved to midline tip. **D**: Six-month postoperative view.

Melolabial Flap

The interpolated melolabial flap is designed with a distinct pedicle based superiorly through the perforators off the angular artery. The skin paddle is located on the medial cheek area and will have an excellent match to the normal nasal skin (Fig. 177.6). The flap is initially elevated in the subdermal plane, becoming progressively thicker as it ascends superiorly into the pedicle proper. The skin paddle must be kept thin with only a layer of subdermal fat. The pivot point for the pedicle is located along the nasal facial groove, and, although the skin incisions are narrowed superiorly to facilitate rotation, the subcutaneous portion remains thick and bulky. The vascular basis of this flap is via perforators within the subcutaneous fat and levator labii superioris, not the skin itself. After the flap is transferred, the melolabial fold is re-created with medial advancement of the cheek. Pedicle division is performed after a 3-week interval to allow for neovascularization from the recipient bed into the skin paddle. The stump of the pedicle is usually excised and donor site closed primarily, leaving a single scar along the nasofacial junction. This is done at the risk of creating subtle facial asymmetry

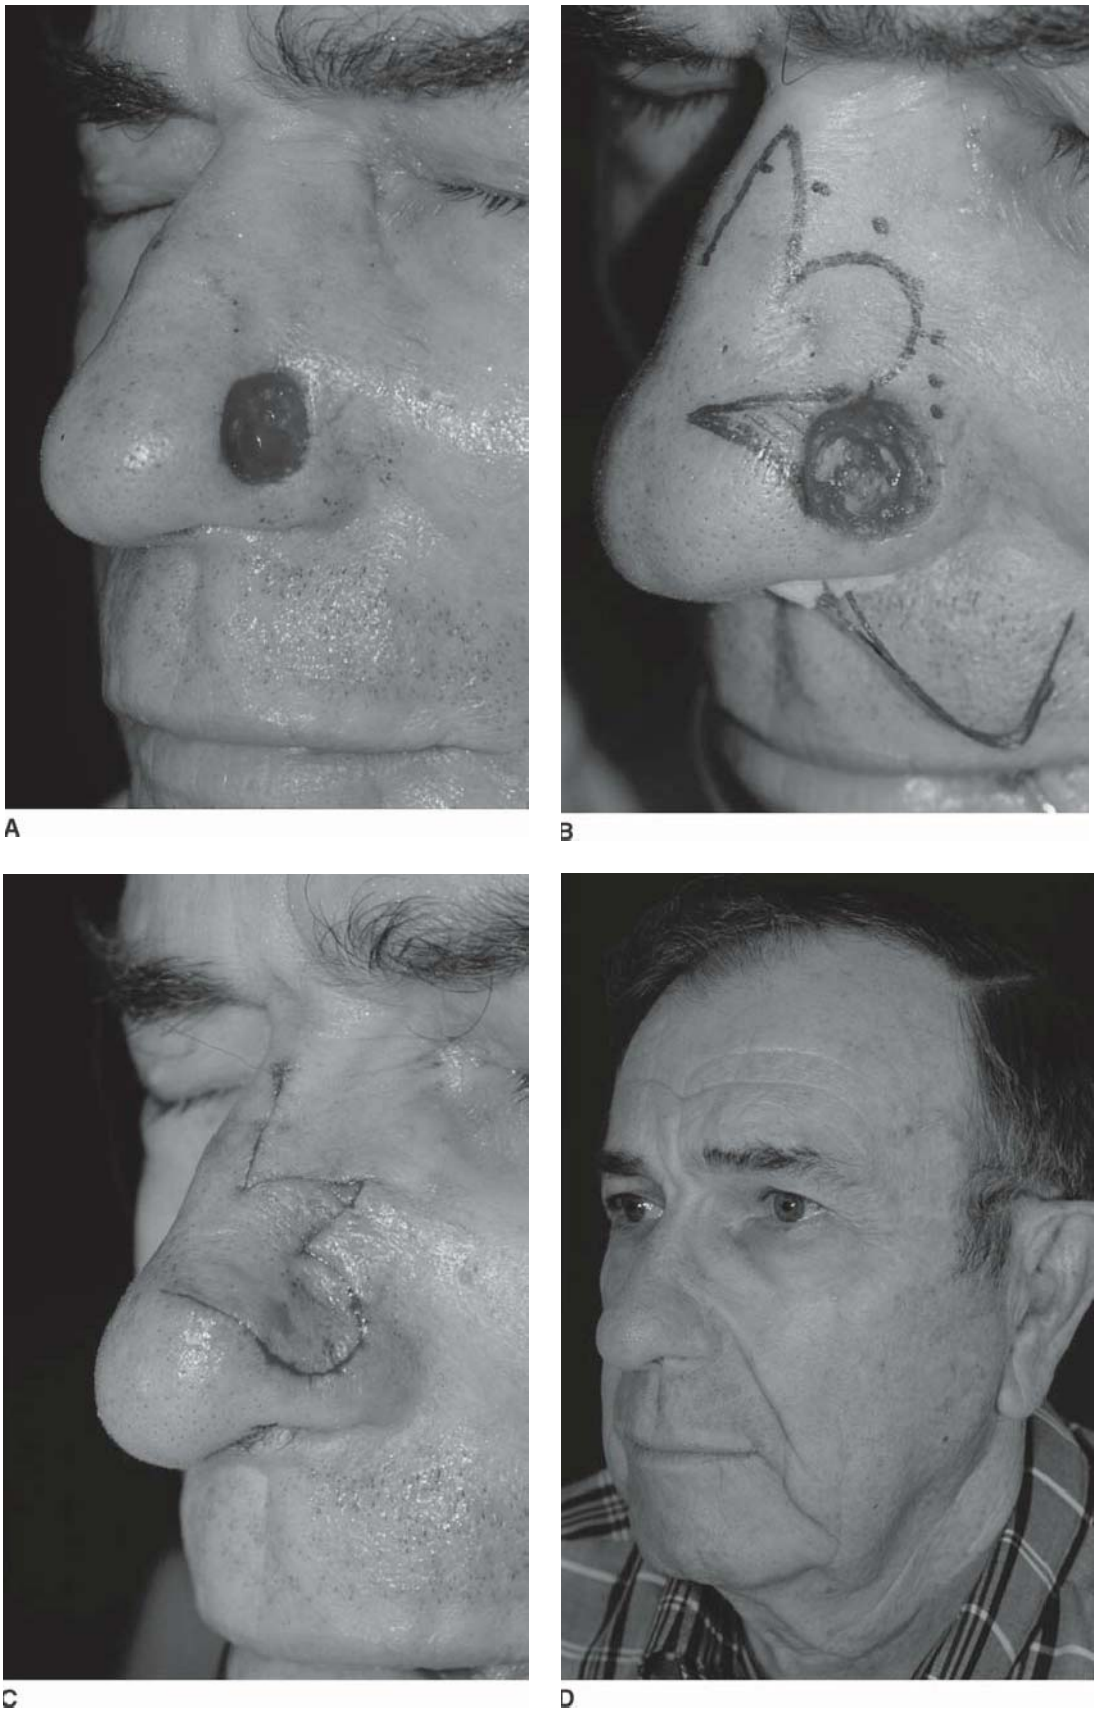

Figure 177.5 Nasal bilobe flap. **A**: 1.3-cm cutaneous defect of left ala and sidewall. **B**: Bilobe flap design. **C**: Flap transposed. Note that the secondary flap is left as a triangle rather than a curved lobe. Straight lines and sharp corners camouflage better. A cartilage batten graft was also placed (not shown). **D**: Six-month postoperative view.

between the two melolabial folds. Alternatively, the pedicle can be returned to the midface, although this will create two oblique scars, one being within the cheek facial unit. The melolabial flap is ideally suited for smaller defects of the alar lobule and columella. It can be extended to the nasal sidewall and nasal tip. It brings vascularized tissue that can cover a cartilage graft. By being based on the cheek, it avoids the functional inconvenience created by a forehead flap pedicle, such as with eyeglasses.

LARGE CUTANEOUS DEFECTS

Preoperative Considerations

Most large skin defects are addressed with more elaborate, interpolated flaps, but on occasion, less invasive options can still represent the most practical means of repair. There are individual considerations that might discourage a more aggressive procedure. Advanced age, significant small-vessel disease, previous radiation therapy, and overall patient health, all might preclude a lengthy and more involved surgical intervention. A large skin graft to the nose may represent the most practical repair for select patients, and, at times, the outcomes can be surprisingly satisfactory. In addition, individual patient expectations and postoperative cooperation should be clearly defined. Although the optimal aesthetic outcome is often the surgeon's goal, patient needs may be quite different, with a much lower cosmetic concern and greater priority toward a speedy recuperation. The logistical inconveniences to the patient, especially with a staged procedure such as an interpolated forehead flap, must be appreciated. The pedicle will often preclude the use of eyeglasses, rigorous work outdoors (which many of these patients may do), and many public positions of employment, for example, waiters, receptionists, and so on.

Simultaneously, when selecting a simpler alternative for short-term convenience purposes, it is important to communicate the aesthetic and functional sacrifices that are being made. A month of inconvenience may be small when contrasted with an outcome that is lifelong. This too must be clearly communicated. A majority of the larger nasal defects occur on a more elderly population, and one certainly needs to develop a feel for their surgical candidacy, level of support, and emotional expectations. For some individuals, a simpler covering such as a full-thickness skin graft will meet their needs as long as they do not develop significant nasal obstruction. On the other hand, there are many senescent patients who remain socially active and are entirely deserving of the optimal repair. Even patients in their eighth and ninth decade of life may have an additional life expectancy of greater than 10 years, and an aesthetic and functional repair will be borne for many meaningful years. This is especially true when weighing the total additional time and morbidity consumed by the more elaborate repair versus the simpler one; a forehead flap brings only a few additional weeks of recovery. The subtotal and total nasal reconstructions require a period of significant convalescence, irrespective of age. The chronologic age of most patients has only a minor role in the decision making for a major nasal restoration.

Forehead Flap

The most common method of nasal resurfacing for large (1.5 cm) defects is with the forehead flap. Despite its ancient origins, this flap remains the major workhorse, as it fulfills many of the criteria for the ideal facial flap. There is an excellent match in color and skin texture and sufficient donor skin to resurface the entire nose. This flap is dependable and robust, leaves an acceptable donor site morbidity, and is, in short, the gold standard for contemporary major nasal restoration (25). Several pearls can aid with the design and execution of a forehead flap (Table 177.4).

Defect Preparation

The nasal aesthetic subunits are drawn directly on the nose at the onset of surgery, irrespective of the preexisting nasal defect. Although the general topography is similar from nose to nose, each individual has intrinsic variations of their nose that must be recognized. This is especially true when there is marked dorsal asymmetry or ethnic variations. As the subunits are defined on the nose, great attention is made to preserving the sharp corners at the border of each subunit. There is a tendency to round the corners during each of the stages of repair, beginning with drawing the subunits to creating a flap that fits the modified defect. Based on the size and shape of the cutaneous defect, it is then usually modified to complete the corresponding aesthetic subunit such that the resultant scars lay along the borders of these subunits. This usually involves enlarging the existing defect. This principle is applied liberally yet not exclusively. When only a small portion of a given subunit is involved (usually 10%), it may be more practical to modify the shape by enlarging the adjacent subunit and thereby minimize excessive resection of normal tissue. This is especially true when the additional subunit will significantly lengthen or widen the skin paddle of the forehead flap. Another exception to the aesthetic subunit principle is a midline vertical scar of the upper two-thirds of the nose; although this bisects the dorsal subunit, the casual observer also sees the face and nose as two halves, and a vertical line between them can remain inconspicuous.

Asian patients, although rarely afflicted with cutaneous malignancies, have a nasal topography slightly different from most occidentals, particularly in terms of dorsal and tip projection, and the subunit principle should reflect that (26). Their nose tends to be proportionally smaller, and there may not be sufficient nasal skin to cover even defects less than 1.5 cm. Under these circumstances, one may need to complete the aesthetic subunits and resurface with a regional flap from the forehead.

The *nasal–facial junction* lies more medial on the "nose" than first impression, and it is one of the sacred borders that should not be crossed. The cheek flap should be brought up to the junction and suspended to the periosteum of the piriform aperture and even to the bone itself if necessary. Crossing the aesthetic border often creates a degree of facial asymmetry and becomes more conspicuous.

Preexisting nasal deformities can influence the surgical outcome and should be recognized with consideration for adjustment during defect preparation. Aesthetic units are defined, in large part, by the reflections of light that arise from contour changes. A twisted nose will have asymmetric and irregular subunits that do not support the aesthetic subunit principle as well, and one might consider correcting the deformity and restoring symmetry and balance to the nose. It can be an opportune time to straighten the dorsum with osteotomies, reduce a prominent hump, or refine a broad and amorphous nasal tip. Through the combination of traditional cosmetic rhinoplasty maneuvers and basic reconstructive tenets, the surgical outcome can be enhanced.

The *depth of the defect* (and the associated subunits) is always taken down to the perichondrium of the cartilaginous framework, even if the primary defect is more superficial. This allows one to shape the exposed cartilages with sutures and conservative resections. Moreover, the forehead flap is often plagued with being too thick, and increasing the depth of the nasal defect will allow a better contour match between the nose and the flap. The additional resection will also only improve the recurrence rate from the original Mohs surgery. It has been suggested that for high-risk individuals, the adjacent subunits be analyzed for occult cutaneous malignancies, as the skin has been exposed to the same degree of actinic injury (27).

1. Modify defect shape with consideration of subunits involved.
2. Create precise 3-D template.
3. Aggressive thinning of distal skin paddle.
4. Narrow pedicle base (<1.5cm).
5. Consider functional grafting.
6. During pedicle division, thin the upper flap and set brows at same levels.

Template

A precise template is made of the final cutaneous defect utilizing the aluminum package from a suture. This can be somewhat laborious but is imperative to get an accurate, *three-dimensional* map of the defect and corresponding skin paddle. One can use the contralateral side as a reference to ensure nasal symmetry. Care is taken to cut straight edges and crisp corners of this template, which is then transferred to the forehead for an accurate tracing. The vertical position of the template is determined by measuring from the medial aspect of the brow down to the nasal defect, recognizing that the length-limiting point is not always the most inferior aspect of the wound but may be the proximal, contralateral corner. The template design is precise and ensures no wasted skin from the forehead. Incisions are made along the internal margin of the markings. Murrell

et al. have described the application of a three-dimensional pattern using Aquaplast (WFR/Aquaplast Corporation, Wyckoff, New Jersey) to transfer a more aesthetically precise template (28). Once the template has conformed to the contour of the patient's nose, it is converted to a two-dimensional tracing on the forehead.

Anatomic Basis

The blood supply to the forehead flap is primarily through the supratrochlear artery, but not exclusively (29). This artery is a terminal branch of the ophthalmic, from the internal carotid system. It exists from the supratrochlear notch or, less frequently, foramen and courses superiorly between the corrugator muscle deep and the orbicularis oculi muscle superficially, finally piercing the orbicularis roughly 1.5 cm above the notch. The artery then anastomoses extensively with the contralateral supratrochlear and ipsilateral supraorbital vessels. The forehead vessels have a dependable axial pattern in the vertical direction, running immediately superficial to the frontalis muscles, and give this flap an axial pattern vascular basis in addition to the named pedicle artery. The pedicle is centered on the supratrochlear vessel but has more than that artery supplying it; the driving anatomic basis for this flap is the robust perfusion pressure located along the medial brow area. The terminal branch of the angular artery supplies the pedicle base and is a major contributor to the arterial supply of the forehead flap. Silicone rubber casts were created from a forehead flap after cannulation of the facial artery alone, that is, no fixative was injected in the internal carotid system. This demonstrated the extensive network of collateral vessels in the medial brow region and a significant perfusion into a forehead flap without flow from the supratrochlear artery (Fig. 177.7) (29).

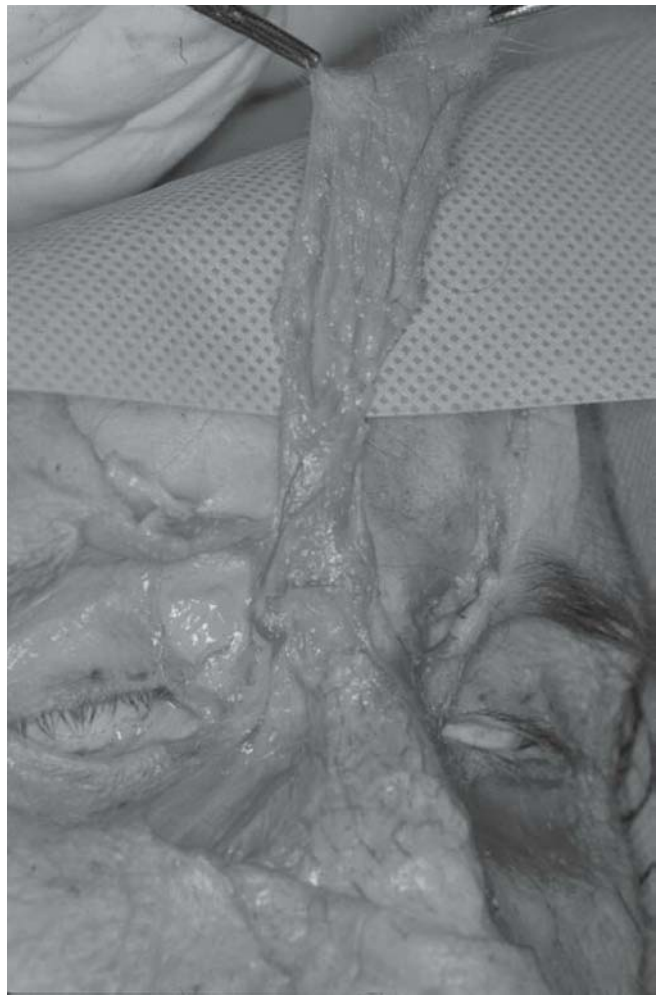

Figure 177.7 Cadaveric study with facial artery cannulated, showing perfusion of forehead flap through angular artery and collateral flow at medial brow area. No dye is from supratrochlear vessel.

Midline Versus Paramedian

The skin paddle of the forehead flap can be placed in the paramedian position, immediately centered on the supratrochlear artery (30). This has the advantage of incorporating much of the artery within the pedicle and, in theory, improves flap viability. Some individuals have a low "widow's peak," and the paramedian design can avoid it. The skin paddle can also be placed in the precise midline, creating a "midline forehead flap," with some discrete advantages (31). The pedicle is still based on a *unilateral* medial brow area, but it diverts obliquely to course in the middle of the forehead. This pedicle design will not incorporate as much of the supratrochlear artery, but the vertical axial pattern of the subdermal plexus remains. The advantage of this design is that the resultant scar will be in the exact midline of the forehead, rather than paramedian. Like the aesthetic subunits of the nose, the face is also visually divided into two halves. The midline vertical scar, despite being perpendicular to the horizontal forehead furrows, is often quite inconspicuous. There is also a natural divergence of the frontalis muscle in the superior forehead, causing the forehead furrows to be discontiguous between the left and right sides. The midline vertical scar tends not to disrupt these and allows better scar camouflage. In addition, the pedicle base has a curved and oblique path rather than the straight vertical design of the paramedian flap. The former allows a slightly longer reach caudally that can be significant with a low hairline or when reaching the alar rim or columella (Fig. 177.8).

Pedicle Design

It was originally thought that the forehead flap pedicle needed to be wide enough to capture both supratrochlear vessels in order to survive. It has later been shown that this forehead flap can be raised off only a single supratrochlear artery and that the pedicle can be safely narrowed to 1.5 cm without jeopardizing viability (14–17). The pedicle for the flap can be based either ipsilateral or contralateral to the nasal defect (assuming it is not midline). Each has its unique advantages. The ipsilateral pedicle is closer to the defect and permits a shorter pedicle length, which can be very advantageous in people with a low hairline. The contralateral pedicle has a longer reach but less rotational arc, thus reducing the amount of twisting that occurs at the pedicle base and possibly

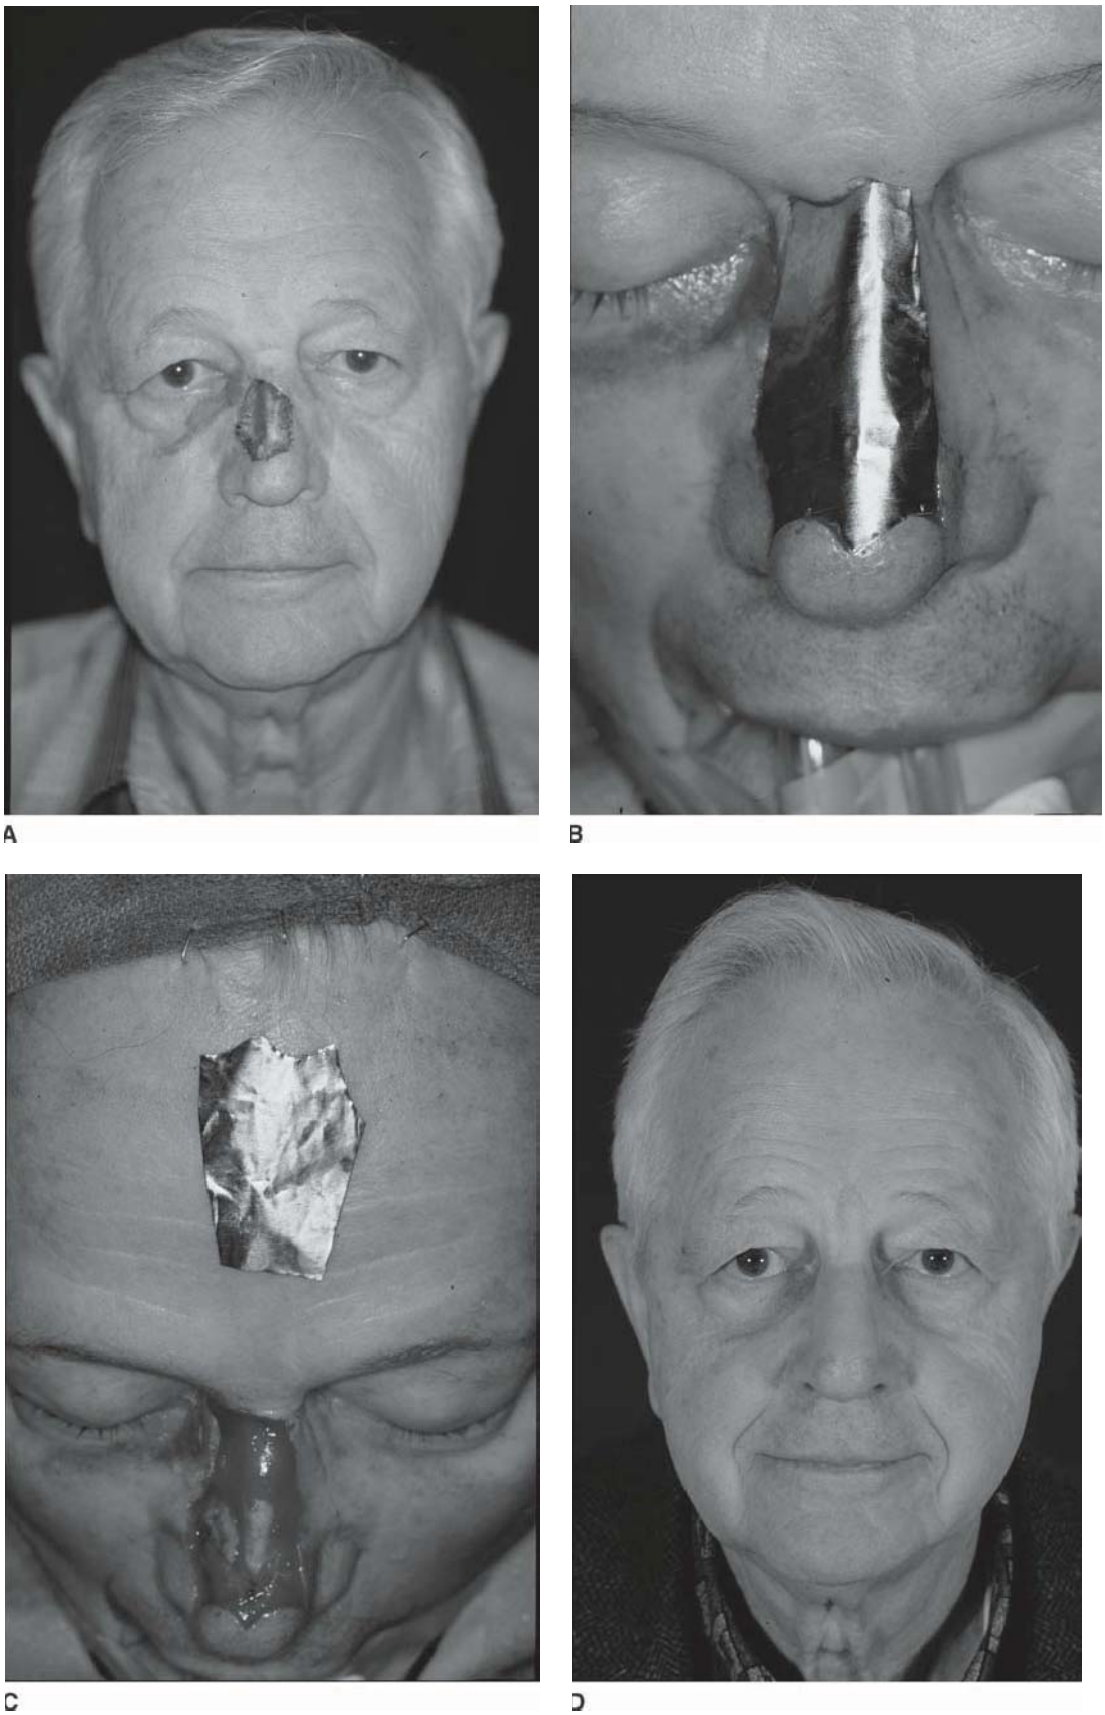

Figure 177.8 **A**: Nasal defect anterior view. **B**: Three-dimensional template of nasal defect (suture package). **C**: Template transferred to precise midline of forehead. **D**: Postoperative view, noting preservation of bilateral forehead furrows and brow symmetry.

improving venous return from the flap. All else being equal, the contralateral flap may be safer and more robust.

Doppler confirmation or localization of the supratrochlear artery is rarely needed, especially because the perfusion pressure and extensive collateralization is a major driving factor. The notch of the supratrochlear vessels can usually be palpated and the skin pedicle centered there. The pedicle base can also be just based on medial brow where the supraorbital rim joins the lacrimal bone. One can include a cuff of periosteum at the base of the pedicle. This serves to give the flap a small amount of additional length. It also provides some rigidity to the pedicle base.

The base of the pedicle should not exceed 1.5 cm, which provides ample vascularity yet does not strangulate the pedicle or hinder the flap rotation. Most flaps can be narrowed to closer to 1 cm at the proximal end. The pedicle can also be extended into the brow and lower glabellar area for additional length.

Skin Paddle Elevation and Thinning

One of the common problems with the forehead flap of years past was excessive bulk, often sacrificing normal nasal form for fear of compromising viability. One of the greatest modifications and advancements made with the forehead flap may be the realization that the skin paddle can, and should, be thinned aggressively during the initial stage (Fig. 177.9). In most cases, the distal skin paddle of the forehead flap is elevated in the subcutaneous plane rather than the subgaleal plane, lifting the flap off the frontalis muscle. The galea (frontalis muscle and fascia) is left down on the forehead during this initial flap elevation. This continues for approximately 25% of the skin paddle, after which the plane is dropped to the subgaleal level and continues effortlessly. The proximal part of the skin paddle will be thinned in the future, during pedicle division 3 weeks later. Once the flap is up, additional thinning is performed to match the intrinsic variations of normal nasal skin thickness. That portion corresponding to the thin rhinion skin, columella, or alar rim is further thinned directly. Axial, subdermal vessels are often encountered within the galea during this process, and the thinning can continue around them without sacrificing the vessels themselves. With healthy patients, the flap thinning will continue to the subdermal layer and fluctuate slightly to best match the variability in native skin thickness. Leaving the frontalis on the forehead donor area has the distinct advantage if the donor site cannot be closed primarily. Second-intention healing will proceed much more rapidly over the galea rather than over the periosteum.

An exception to this method of elevation is in smokers or other individuals with small-vessel disease. For these high-risk situations, the skin paddle is elevated with the bulky subgaleal layer and transferred en bloc. An *intermediate stage* is used to thin the flap (discussed later).

Donor Site

A great majority of forehead defects less than 3.5 cm can be repaired primarily through wide, subgaleal undermining

Figure 177.9 Elevation of distal forehead flap in the thin subcutaneous plane rather than subgaleal plane. Thin layer of fat is preserved under skin paddle of flap. This thinning continues only for 30% of the skin paddle and is not performed in smokers.

out to the temple areas. Deep sutures must be through the galeal layer in order to ensure sufficient strength; it is often necessary to place all the deep sutures prior to closure and tying of sutures. The standing cutaneous deformity at the superior border is directly excised in a vertical fashion with the incision extending into the frontal hair. Alternatively, the forehead can be mobilized and closed in an "O to T" fashion with a horizontal limb at the hairline. Like a trichophytic browlift, this can be closed in a running "W-plasty" to further camouflage the scar.

For wider defects, vertical galeatomies may allow additional recruitment from the sides. Any remaining defect on the forehead is allowed to heal by second intention. The resultant scar following wound contracture will generally be superior to other methods, especially when the galea has been left in place. A skin graft will allow that area to heal quickly but generally remains more noticeable. Early tissue expansion has been described as an alternative for the tight forehead or the low hairline (32). Although this does create an abundant amount of tissue and permit primary closure following wide forehead flaps, the expanded

skin is less favorable in terms of flap physiology. Some flap contracture will occur, even following direct excision of the expander capsule, and will compromise the final nasal form.

Pedicle Division

The pedicle is the obligatory nutrient supply for the skin paddle until sufficient neovascularization occurs from the recipient bed into the flap itself. Vascular ingrowth is predictable and is driven, in part, by the ischemic gradient between the nasal defect and the distal flap (33). There is probably sufficient support for the flap after a 10-day period, but a 3-week interval is allowed to lapse to ensure greater fibroblast development, increased tensile strength, and adequate adherence of the flap to the nose. The pedicle is divided transversely, a few millimeters above the original nasal defect. Undermining proceeds in a superior-to-inferior direction, immediately under the dermal plane, to roughly halfway down the skin paddle. One can leave the subcutaneous portion of the pedicle intact, allowing it to provide countertraction as the skin is undermined. The bulk of the subcutaneous tissue is then removed while tapering the inferior border to smooth the transition. It is imperative to debulk this portion of the flap and allow the flap to conform to the normal nasal topography. The edges of the original nasal defect are carefully freshened and corners are squared off. Over the preceding 3 weeks, the border of the defect will have contracted and started to reepithelialize.

The superior stump of the pedicle is then trimmed accordingly and inset back into the glabellar area. There is a tendency for this portion of the pedicle to thicken and pincushion. Aggressive thinning of the corrugator muscle contained in the pedicle stump will help minimize this. It is essential to restore symmetry to the eyebrows, as the pedicle side tends to be pulled inferiorly. After the medial brow is resuspended, the new standing cutaneous deformities can be directly excised. The inferior forehead scar can be revised readily at this time. The scar in this area is often inverted and conspicuous there because a wide frontalis muscle portion is included in the pedicle. On occasion, one can dermabrade some of the scars of the nose or the forehead at this relatively early stage (Fig. 177.10).

Three Staged Forehead Flap—with Intermediate Stage

In higher-risk individuals such as smokers, the original forehead flap can be transposed as a composite of skin and frontalis muscle, without preliminary flap thinning, with a planned *intermediate stage* (34). During this step, the skin paddle is elevated from laterally on both sides, leaving the original forehead flap as a bipedicled flap, attached at the medial brow proximally and the nasal tip distally. The flap is then thinned and sculpted to the appropriate level to restore nasal form (Fig. 177.11). An additional 3 weeks are allowed to pass before the final pedicle division is performed. While this methodology leaves the pedicle intact for 6 weeks, the inconvenience is justified by improved flap viability and better outcomes within a high-risk patient group. The flap can also be elevated more aggressively, including the distal tip. This essentially converts the forehead flap into a delayed flap.

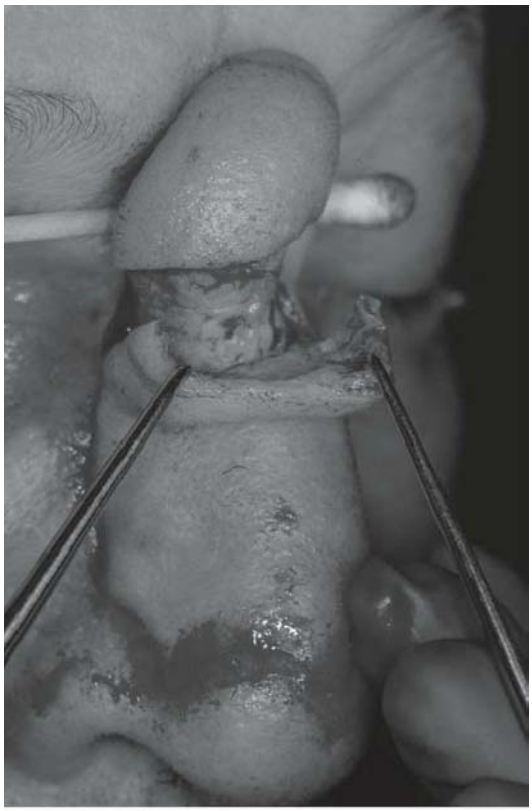
Single-Stage Forehead Flap

The single-stage forehead flap (Table 177.5) utilizes a deepithelialized pedicle and was originally described by Converse in 1963 as a modified median forehead flap based on both supratrochlear vessels (35). It had problems with a limited arc of rotation and flap congestion and was subsequently abandoned. Utilizing what is known today about the robust vascularity of the contemporary forehead flap, one can create a single-stage, island forehead flap based on a *unilateral* medial brow area (36). This single-stage flap has a similar anatomic basis as the conventional, interpolated forehead flap but does not require a pedicle division. The advantages of accomplishing a major nasal resurfacing in a single stage can be tremendous for those patients in whom the pedicle and need for a second surgery create a hardship that is difficult to overcome. The vascularity from a subcutaneous pedicle is, however, more tenuous, and this type of forehead flap should be avoided in high-risk individuals, such as smokers and individuals with small-vessel disease.

Both a unilateral supratrochlear artery and the rich collateral supply from the angular artery provide the perfusion pressure that supports the skin paddle. It should be based on the contralateral side to avoid excessive torsion on the pedicle. This flap is converted to an island flap as the glabellar skin is carefully dissected off the pedicle. Tremendous care must be taken to avoid inadvertent changes in plane during this stage because pedicle amputation is the result. The glabellar skin is undermined widely, and the resultant tunnel is connected to the defect of the nose. Portions of the procerus muscle can be resected in order to create sufficient room to accommodate the pedicle without compression and congestion. The flap is then tunneled under the intact glabellar skin and the skin paddle delivered into the nasal defect then closed completely in a circumferential fashion. The donor site is closed primarily, often incorporating a W-plasty inferiorly that parallels the natural glabellar furrows. There is a soft tissue void where the subcutaneous pedicle was originally located, and portions of the frontalis muscles can be mobilized to fill this depression and improve glabellar contour. This flap works best for nasal defects limited to the upper two-thirds of the nose; nasal tip and alar defects require a lengthier forehead flap and may not remain viable (Fig. 177.12).

STRUCTURAL SUPPORT AND GRAFTING IN NASAL RECONSTRUCTION

In addition to the surface area of a nasal defect, it is imperative to determine its depth and location in terms of its impact on nasal function and form. Structural grafting



A

B

C

Figure 177.10 Pedicle division. **A**: Skin elevated with subcutaneous portion intact, providing temporary countertraction. **B**: Debulking subcutaneous portion. **C**: Pedicle inset with attention to brow symmetry.

is placed for three primary reasons: first, to provide rigidity to the sidewall, thus preventing collapse and nasal obstruction; second, to create or maintain form, especially along the alar rim and tip; and third, to provide dorsal support and projection. Many small and superficial defects of the lower third of the nose are repaired with composite grafts, thus providing a covering and support simultaneously. Larger and more complex defects usually require separate support grafting and an independent resurfacing flap.

Nasal Function

New onset nasal obstruction can compromise an otherwise excellent surgical outcome and be the source of significant patient dissatisfaction. Predicting those lesions that will lead to nasal obstruction is important and is influenced by both the defect's depth and its location. When the depth is such that native structural support has been removed (e.g., a portion of the lateral crus), the defect will uniformly require reconstruction with some form of cartilaginous grafting. An exception is small defects of the nasal bones, albeit rare. Lesions located over the alar lobule or nasal sidewall are particularly prone to collapse and subsequent nasal obstruction at the level of the internal and external nasal valves. There is a critical area located at the junction of the two anatomic valves, corresponding to the supra-alar crease externally and the area lateral to the lateral crus internally. There may be a free-floating sesamoid cartilage in this area, which is characteristically just a firm, fibrofatty aponeurosis between the lateral crus and the bony piriform aperture. In this area, even small defects that violate the fibroareolar tissues will tend to collapse, especially following local transposition flaps. Therefore, it is not solely the size of the defect but the depth that may be the indication for structural grafting (21). Lesions within the ala or sidewall often require a repair that involves some rigidity. Straight septal cartilage works well for support to the lateral nasal wall of the middle vault, and conchal cartilage is most often used for the alar lobule.

One can enhance nasal airflow by placement of a *flaring suture* across the upper lateral cartilages (37). The middle nasal vault is often exposed during nasal reconstruction and subject to contractile forces. Because of the concavity over the dorsum, this can lead to subtle pinching of the middle third of the nose and some degree of narrowing at the internal valve. The flaring suture placed across the dorsum serves to hold open the upper lateral cartilages during the healing process and support the airway. A long-lasting suture is placed as a horizontal mattress across each upper lateral cartilage, with the dorsal septum serving as a fulcrum. As the suture is tightened, the upper lateral cartilages will flare upward and outward, thus opening the internal nasal valve (Fig. 177.13). This can be placed during any nasal reconstruction where the upper lateral cartilages become exposed, even with smaller procedures such as a bilobe flap.

TABLE 177.5 PEARLS FOR THE SINGLE-STAGE FOREHEAD FLAP

1. Select patient carefully.
2. Create adequate room under glabellar skin.
3. Fill forehead depression with procerus and frontalis muscles.
4. Watch for flap congestion.

Grafting for Form

The alar rim is one of the free margins that represent an "immobile landmark" during defect analysis. Normal wound healing and contracture will tend to pull the alar rim up and create a notch deformity; preserving alar base symmetry is one of the greater challenges in nasal restoration. Any defect that encroaches on the free margin of the ala will require some form of structural support to resist the powerful wound contracture that ensues. The curve found along the inferior conchal bowl conforms well to the natural shape and curl of the alar lobule. Grafts may also be placed at the nasal tip to improve definition and form. Many of the common tip grafts used in aesthetic rhinoplasty can be employed here with equal success.

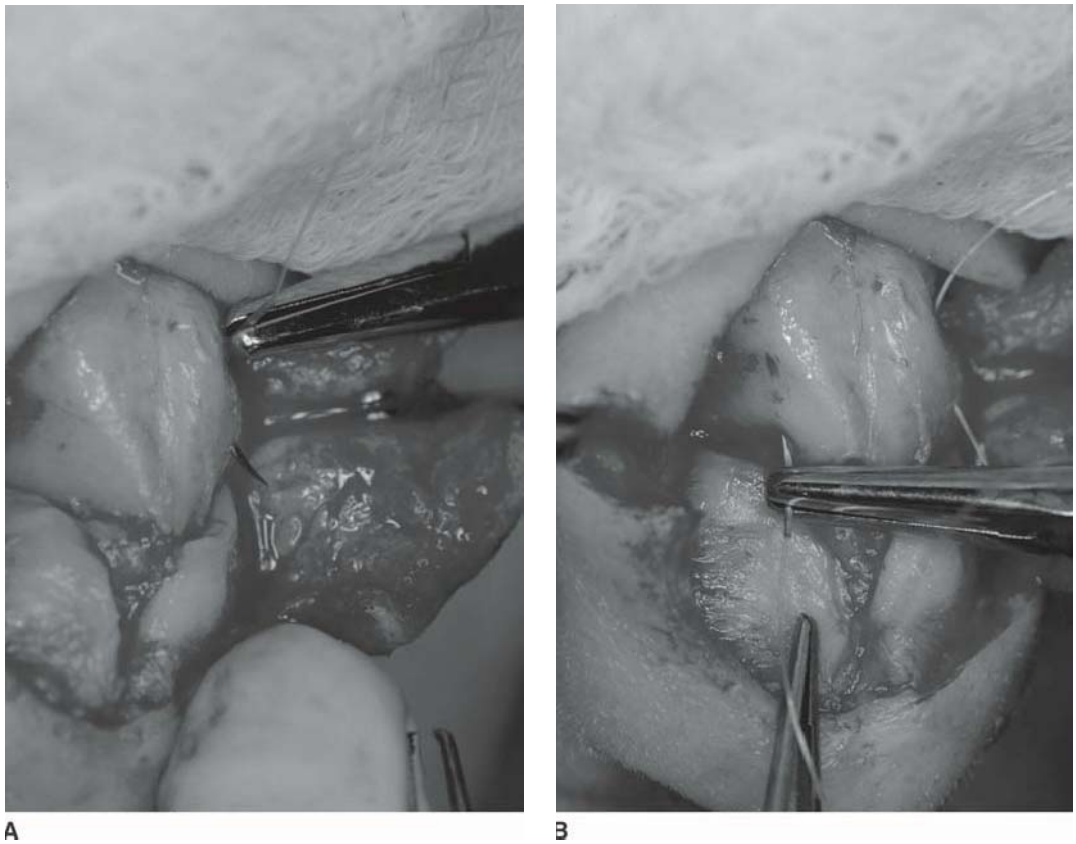

Figure 177.13 **A**: Flaring suture passed through left upper lateral cartilage. **B**: Through right upper lateral cartilage. **C**: Tied-over nasal dorsum to flare open the internal nasal valves.

Because the covering flap tends to be thicker, one can exercise tip refining measures with minimal risk of creating an unnatural "unitip." Traditional shield or cap grafts should be sutured secured to the underlying structure. Grafts to the tip can also serve to stabilize the junction of a reconstructed framework, such as the union between alar rim grafts and the midline support (e.g., columella). Bridging the junction of cartilage grafts creates substantial more stability than a primary, end-to-end union of grafts alone.

Large lesions may remove portions of the midline dorsal support, and its reconstruction can be more complex. Unlike a dorsal augmentation during the correction of a saddle nose deformity, this reconstruction must bring sufficient rigidity to support the cutaneous and *intranasal* dorsum. This can be accomplished by one of three mechanisms: septal cartilage, cantilevered split calvarial bone, or costal cartilage grafting. Some complex nasal lesions extend on to the cheek, not only cutaneously but also to involve framework. If portions of the premaxilla or lateral bony piriform aperture have been resected, they must be individually repaired in order to recreate a solid platform for the nose. Failure to do so will lead to progressive collapse of the nose. The bony aperture of the nose is an essential foundation upon which other structural grafts and flaps can be added (Fig. 177.14).

Techniques for Grafting

The *middle vault and sidewall* areas are ideally reconstructed with straight *septal cartilage*. This material is readily available and should be long enough to rest on the bony piriform aperture laterally and reach the midline dorsum. The *alar lobule* is best supported by autogenous *conchal cartilage*, but it must be carefully sculpted. It can be harvested through either the anterior or posterior approach with little risk of creating significant donor site morbidity. Like septal cartilage, the conchal cartilage graft must be sufficiently long to rest on the bony, medial buttress and extend up to the existing cartilages or close to the midline. Small discs of cartilage grafts will tend to fall intranasally and not function as the batten that is needed. For these cartilage grafts, one creates small subcutaneous pockets under the supra-alar crease or within the alar lobule, but only blunt dissection should be performed in this area in order to minimize risk of injury to the lateral nasal artery. The medial border is firmly anchored to the tip cartilages in an overlapping manner. The superior margin of the graft should be slightly more medial than the inferior margin, forcing the plane of the graft to mimic the contour of the lobule and create a supra-alar crease. In order to maintain the vertical height of the alar rim, one should ensure that the caudal border of the graft is positioned sufficiently inferior, anticipating

A B

Figure 177.14 **A**: Large left heminasal and cheek defect involving maxilla. **B**: Split calvarial bone to reconstruct medial buttress, providing platform for nasal base.

the vertical contractile force of wound healing. Grafts are suture-secured to the intranasal lining with through-and-through sutures, thus pulling open the airway under the graft. The natural curvature of the cartilage holds the airway patent, even slightly over corrected. The ala will also feel unnaturally firm with respect to the contralateral side, but this is anticipated and ensures patency at the valves (Fig.177.15).

Dorsal reconstruction can be achieved through a *composite septal flap*, pivoted out of the nose with a hinge along the anterior nasal spine. A full-thickness incision is created through the nasal septum, along the dorsum superiorly, vertically posteriorly, and off the maxillary crest inferiorly. This allows the septum to hinge anteriorly and outward as a composite flap composed of cartilage and bilateral mucosal flaps, bringing structure and internal lining simultaneously. A small wedge of septal cartilage should be excised at the posterior septal angle to facilitate the outward pivot. It is imperative that the septal branch of the anterior septal artery be intact, as it is the primary blood supply to the flap. Each vessel can support the entire ipsilateral septal mucosa and underlying cartilage. Once the composite flap is rotated outward, it is secured with permanent sutures to the residual dorsum and the anterior nasal spine. Septal splints may be useful to provide additional support during the healing phase, reducing the risk of lateral displacement and nasal obstruction. By necessity, this three-layered septal composite flap will leave behind a permanent septal perforation. Although this adds to the convalescence, only rarely is it symptomatic after healing. This technique works well for reconstruction of large, complex, and full-thickness defects of the dorsum, tip, and columella (Fig. 177.16).

Costal cartilage and *split calvarial bone* are excellent structural grafts for total dorsal reconstruction. Nasal defects of this magnitude are usually associated with deficiencies of internal lining, which will always require an independent flap. Cartilage can be harvested from either the seventh, eighth, or ninth rib. Most skin incisions do not need to exceed 4 cm, and the rectus abdominis muscle can be split rather than transected, thus reducing the postoperative pain. A straight portion of the rib should be harvested and only the precise central core utilized for grafting, as eccentric portions of a rib graft will progressively warp. Graft resorption, displacement, and *in situ* warping are the more common complications that can arise. Split calvarial bone is similarly abundant and generally harvested from the straight parietal region of the skull. Its edges are carefully beveled with a drill, and it may be secured at the nasion with a lag screw technique. Both calvarial bone and costal cartilage will leave the nose feeling unnaturally rigid and immobile. It should be supported at the caudal end with an extended columellar strut graft and laterally with conchal cartilage grafts. This lateral support is essential to reduce inward collapse as well as to camouflage the lateral borders of the dorsal reconstruction graft.

INTERNAL LINING DEFICITS

The complexity of a nasal defect is dictated as much by its depth as by its overall size. Violation of the internal lining of the nose is one of the major variables that elevates the complexity and level of sophistication of the repair. It can be tempting to disregard the lining and simply address the structure and covering flap. This is misleading since the immediate result can be quite acceptable but long-term outcomes are uniformly unfavorable. Previously, a preliminary stage was performed in which grafts and internal lining were buried under the forehead as a first stage. This failed because of its lack of flexibility after the flap was transposed. The purpose of a meticulous repair of all lining defects is twofold: First, a vascularized internal covering is needed for structural grafts (e.g., conchal cartilage batten grafts), and, second, second-intention healing of intranasal areas will lead to alar notching and cicatricial stenosis, progressing to a compromise of form and function. Consequently, even small perforations of the intranasal mucosa must be addressed in some manner. Not infrequently, many options for lining repair have been eliminated by the nature of the defect, and one must proceed down an algorithm to alternative techniques. For this reason, it is imperative to be facile with a number of different grafts and flaps used for internal lining repair prior to embarking on a reconstruction of this complexity. Being able to predict the involvement of intranasal mucosa is difficult but can be useful. Certain subtypes of cutaneous malignancies are characterized by their aggressive growth patterns and propensity to extend via small isolated nests of cells beyond the gross margins, for example, morpheaform BCCA. It is prudent to recognize this propensity for intranasal involvement and plan the excision and reconstruction accordingly, including the incorporation of Mohs micrographic surgery and anticipation of a full-thickness nasal defect. In addition, one should bear in mind that the intranasal defect represents the surgical margin for the cutaneous malignancy, and close follow-up of this area is imperative. This is most accurately performed with nasal endoscopes, common to the otolaryngologist.

A very small perforation of the internal lining can often be closed primarily with a single catgut suture. It is best to close the deficit vertically rather than horizontally, in order to minimize the propensity to retract the alar rim. Larger defects will require a flap or graft and can be defined based on their tissue origin (Table 177.6). Selecting the proper internal lining flap is challenging and often based on the location of the defect; most grafts and flaps are needed for only the middle third or lower third of the nose (Table 177.7). Only rarely is an internal lining repair needed within the upper third of the nose.

Grafts

Full-thickness skin grafts require a vascularized recipient bed and, as such, will rarely be utilized for internal

Dorsal support is maintained.

TABLE 177.6 OPTIONS FOR REPAIR OF INTERNAL LINING DEFECTS

1. Primary closure (vertical)
2. Grafts
   a. Skin (rare)
   b. Composite (excellent for ala)
3. Cutaneous epithelial flaps
   a. Folded, distal resurfacing flap
   b. Nasal epithelial "turn-in" flap
   c. Second cutaneous flap (melolabial, forehead)
4. Intranasal flaps
   a. Ipsilateral septal mucosa flap
   b. Contralateral swinging composite flap (excellent for middle vault)
   c. Bipedicled "bucket-handle" flap (small caudal defects only)
   d. Inferior turbinate flap
5. Labial mucosal flap (small caudal defects)
6. Pericranial flap
7. Distant microvascular flap

lining repair because of the concomitant need for structural grafts. An exception might be along the upper one-half of the nose, where collapse and contracture are much less of a concern. Many times, second-intention healing will suffice in this area. Grafts from the hard palate have more intrinsic rigidity and may be applied for intermediate size defects.

A composite graft of skin and cartilage from the ear is extremely versatile and can be liberally applied to full-thickness nasal defects. It may be the technique of choice for lining deficits of the distal one-third of the nose, especially the alar lobule, because it brings a thin epithelium to an area that is normally stratified squamous epithelium and includes a structural graft that forms well to the natural contour of the ala. Small defects of the alar rim and soft tissue facet can be repaired with a composite graft harvested from the root of the helix, utilizing the skin on the inner surface of the helix, within the concha cymba. Larger defects that involve the alar lobule are best reconstructed with a composite graft from the conchal bowl. The donor site can often be closed primarily with minimal auricular deformity. Alternatively, a full-thickness skin graft can be secured to the donor site. In both cases, the skin portion of the graft is closely adhered to the cartilage with little intervening fat, thus making it an excellent option for composite grafts. The graft should be firmly secured to the undersurface of the resurfacing flap, entirely obliterating any potential dead space that might arise. A through-and-through bolster is very effective for this purpose (Fig. 177.17).

4. Labial flap

Cutaneous Epithelium

Cutaneous epithelium is an additional source for internal lining repair and has some distinct advantages. Large amounts of tissue can be mobilized to inside the nose with little morbidity. Earlier concerns regarding the nonphysiologic nature of this flap (i.e., bringing keratinizing epithelium to the intranasal space) have not borne out to be problematic. Desquamation, odor, or crusting has not been a major complaint for these patients. There is additional thickness and bulk to this type of flap, and it is important to thin the skin paddle aggressively prior to transposition. Nasal obstruction from a thick flap is difficult to correct secondarily. Perhaps the greatest concern is the mobilization of sun-exposed and potentially actinically injured skin to the intranasal portion of the nose, especially considering the high nature of recurrence or metachronous lesions. The intranasal examination postoperatively is best performed by the otolaryngologist and with a nasal endoscope.

A *second epithelial flap* can be elevated and transposed for internal lining repair. Common sites include a separate melolabial flap or second forehead flap. These are associated with extra morbidity but may represent a viable option for advanced cases (38). Distant tissue through microvascular transfer is a more dramatic means of bringing lining to within the nose. It should be viewed as a preliminary step requiring subsequent stages for thinning and sculpting (39–41).

The *distal portion of the primary resurfacing flap* can be folded on itself to wrap around a cartilage graft and provide internal lining. This utilizes cutaneous epithelium and is subject to the same guidelines in terms of risk of transferring actinically injured skin. The additional morbidity may be minimal for small lining defects since the source of skin may be the superior portion of the forehead. The skin paddle should be thinned aggressively. Moreover, this portion of the forehead flap may include the frontal hair and have to be trimmed regularly. There is concern over the vascularity of this distal part of the flap, particularly after folding it on itself, but the robust vascular perfusion appears to be

adequate. Perhaps the greatest shortcoming has to do with the free margin of the ala. Although the intranasal lumen may be functionally adequate, the alar rim often takes on an unnaturally thick and straight appearance when using this method. This option is not used as often for internal lining repair.

The *epithelial "turn-in" flap* is a versatile flap for internal defects limited to the lower half of the nose, especially the middle third/lateral nasal wall (42). It utilizes the cutaneous epithelium from the upper nose and turns it in 180 degrees, so that it faces intranasally. Elevation begins superiorly in the subdermal plane and descends deeper as one proceeds inferiorly in order to create a flap with a healthy subcutaneous pedicle. The pedicle base requires careful dissection in order to avoid amputation and often leaves an area of bulk and fullness to the external nose. The ideal defect has the intranasal edge in close proximity to the skin edge, allowing for primary edge-to-edge approximation. One must closely survey the quality of the skin prior to elevation and transfer. In some cases, this flap adds no additional morbidity; at times, the "turn-in" flap represents skin that would be discarded during the completion of the nasal aesthetic subunits. It has the advantage of not disrupting the native intranasal mucosa, which can greatly accelerate recovery. It is limited in terms of the amount of skin available and is best suited for smaller internal defects (Fig. 177.18).

Intranasal Tissue

It is ideal to replace tissue with like tissue, and intranasal mucosa has several options that provide a thin, pliable, robust, and physiologic lining for the full-thickness nasal defect. The *inferior turbinate mucosal flap* provides a modest amount of mucosa without major donor site morbidity and can be an excellent flap for defects involving the lateral aspect of the middle or lower thirds of the nose (43). It is rare for a primary cutaneous malignancy to invade so far posteriorly that it disrupts the head of the inferior turbinate. Mesenchymal tumors of the lateral nasal wall, on the other hand, can extend posteriorly to involve the turbinates or even maxillary sinus. The inferior turbinate flap is based anteriorly on its head and is best elevated by first extracting the entire turbinate, including bone, as a flap based anteriorly. The conchal bone is then dissected off and the mucosal flap mobilized to fill the lining defect as an interpolated flap. The pedicle is usually quite short and does not necessarily require revision.

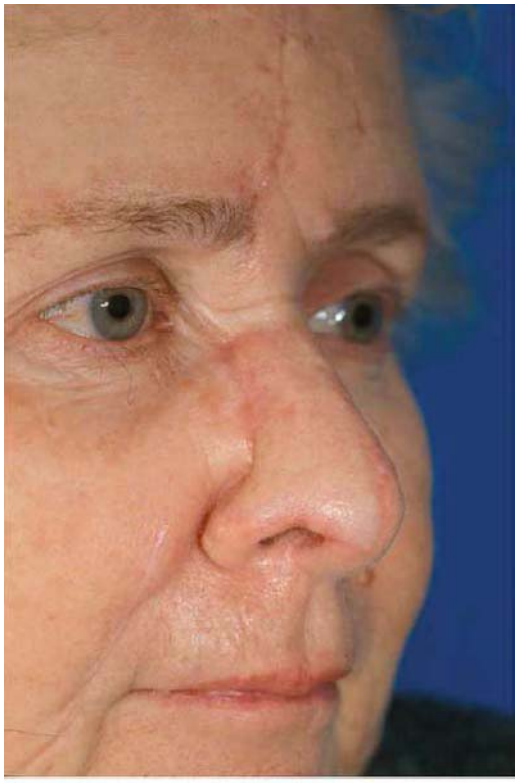
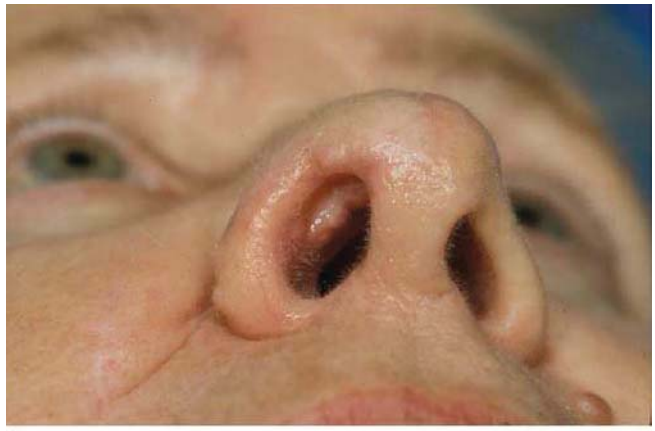
E

F



G



H

Figure 177.18 *(Continued)* **E**: Flap turned in with cutaneous epithelium facing intranasally. **F**: Two-layered composite graft to distal vestibule. **G, H**: Six months showing alar form and patency.

The *bipedicled "bucket-handle" mucosal flap* is an excellent option for relatively small lining defects along the alar lobule. It utilizes intranasal mucosa immediately above the defect and hinges it inferiorly as a flap based medially and laterally. The anterior septal artery territory does not dependably extend laterally to the sidewall, and the lateral pedicle must be maintained. Any contribution from the ethmoid system is severed by flap design. Wide undermining is critical in order to allow complete mobilization inferiorly without superior traction and recoil. A horizontal relaxing incision can be created with an angled beaver knife. The extent of undermining should be to the nasal bones, where the secondary donor site defect is allowed to heal by second intention. Placing a skin graft to this

location is an alternative, but rarely necessary. Any superior retraction will inevitably lift the free alar margin and compromise the alar base symmetry.

The contralateral septal mucosa can be used via a *swinging, composite septal flap*, based on the dorsal septum and the branches of the anterior ethmoid artery. It is an excellent means of providing both intranasal lining and cartilaginous framework to the middle third of the nose. It does not have sufficient size to provide structural framework to the alar lobule. The cartilage is typically straight and can also assist with dorsal support to that area as it rests on the boney ledge of the piriform aperture. The ipsilateral septal mucosa is elevated off the septal cartilage and preserved. A full-thickness incision is then made through the septum, creating a swinging door of cartilage and contralateral septal mucosa, based on a hinge along the dorsum. The cartilage rests lateral to the bony ledge, but the mucosa is sewn directly to the internal lining margin. There is a tendency for the flap to swing back medially, and this is resisted by securing the cartilage to the boney aperture. The ipsilateral septal mucosa can be used for alar lining for larger defects or can be replaced to reconstruct the resultant septal perforation. Occasionally, this area will break down and a perforation will recur.

The ipsilateral, septal mucosa flap is a large flap for complex internal lining defects of the nose. First described by Millard (15) in 1967, it is a thin and dependable flap based on the septal branch of the superior labial artery. The entire septal mucosa is lifted off the cartilage and mobilized to line the lower two-thirds of the nose. Tremendous care should be observed to stay in the correct subperichondrial plane, especially if there coexist septal spurs or fractures. The pedicle to this mucosal flap may cross the nasal vestibule and cause nasal obstruction. This can be divided at a subsequent stage. A large septal perforation may develop but is only rarely symptomatic. The critical prerequisite for this flap is the preservation of the anterior/inferior portion of the septum and the nasal sill, as this functions as the flap base.

Pericranial Flap

The pericranial flap is a thin and versatile flap often used by neurosurgeons for anterior cranial defects. It can also be elevated for internal nasal lining and transferred as part of the forehead flap. The pericranium should be covered with a skin or mucosal graft because, although epithelialization will occur eventually, wound contracture and desiccated cartilage may present problems. The forehead flap can be elevated full thickness (i.e., with the periosteum of the forehead), then split longitudinally to excise the frontalis muscle and create a bifid flap that encapsulates the cartilage grafts of the nose. The pericranium is based on the same pedicle as the forehead flap but is more tenuous and a wider pedicle base may be needed. It can be dunked intranasally during the pedicle division at 3 weeks.

CONCLUSION

Nasal restoration in the 21st century has reached a new milestone that has brought together centuries of experiences, lessons, errors, and rewards. The bar has been set and it is nothing less than full restoration of normal function and complete aesthetic acceptance. The expectations for both minor and major nasal repair include symmetry, natural contour, excellent color and texture match, and a final product that remains inconspicuous to the casual observer. The major tenets that have been realized today include the wide application of the subunit principle, liberal and nonanatomic cartilage grafting, and addressing each of the three layers of the nose diligently and independently. The robust nature of the forehead flap has expanded its applications and lifted the outcomes of major nasal resurfacing. Anticipating resultant scars and vectors of tension are the subtle nuances of local flaps that ensure a pleasing result.

HIGHLIGHTS

- Using a reconstructive *algorithm* can assist with flap selection and avoiding pitfalls.
- Alar base symmetry must be preserved with small flaps, often requiring cartilage batten grafts and careful design.
- Consideration of the aesthetic subunit principle can improve scar camouflage.
- The forehead flap is a robust flap that remains the workhorse for resurfacing large defects.
- Full-thickness defects must address each of the three layers of the nose independently (internal lining, structure, and covering).
- Nasal function is paramount and usually addressed with nonanatomic, conchal cartilage grafts resting on the lateral nasal wall laterally.
- All internal lining defects must be meticulously repaired with flaps or grafts.

Facial Reanimation

178

Tessa A. Hadlock

Rehabilitation of the paralyzed face remains a challenging problem for otolaryngologists, and its proper management may require input from facial plastic surgeons, head and neck reconstruction specialists, otologists, and adjunct medical personnel. Following viral nerve insult, traumatic nerve injury, or intentional sacrifice with repair or cable grafting, regenerative results vary greatly and can lead to hypofunction, hyperfunction, aberrant regeneration, or a combination of these phenomena. The functional problems related to facial paralysis are extensive. In the upper face, they include brow ptosis, leading to a visual field deficit and hygiene issues related to skin desquamation onto the cornea. In addition, loss of a blink reflex leads to corneal exposure of the affected eye, there is lacrimal gland hypo- or hyperfunction, and lower lid paralysis results in ectropion as well as poor lacrimal punctal function. In the central zone of the face, patients may suffer with unilateral nasal obstruction, upper lip ptosis, lack of oral commissure excursion with smiling, oral incompetence to both liquids and solids, and articulation problems. In the lower face, lower lip weakness also contributes to oral incompetence, and platysmal synkinesis can restrict smiling and lead to superficial torticollis symptoms. Facial paralysis also has a significant impact on nonverbal communication, and the loss of one's ability to express positive emotions on the face rivals the above-listed issues as the most dominant source of patient devastation.

Herein, we review the management of facial nerve deficits and describe the surgical management of each distinct zone of the paralyzed face, with regard to recovery potential, prognosis, and patient factors that contribute to surgical decision making. We emphasize the systematic assessment of each facial zone as a critical step to ensure comprehensive management of the paralyzed face (1).

NERVE REPAIR AND GRAFTING

Nerve Injury Classification

Nerve injuries are classified according to the level of microanatomical disruption. According to the Sunderland classification system (2), level 1 injury has no microanatomic disruption but a simple temporary dysfunction of the membrane sodium channels, resulting in transient inability of the nerve to transmit impulses. In level 2 injury, axons are disrupted, though their individual endoneurial channels are not, so that when regeneration occurs, there is little to no axonal misrouting. In level 3 injury, endoneurial sheaths are violated, though perineurium is left intact. Recovery from this type of injury occurs over months and inevitably results in some synkinesis. Level 4 injury implies total perineurial disruption, where only the outer epineurial sheath is intact, and spontaneous recovery is generally poor. Level 5 injury refers to total anatomic disruption, including the epineurium. No spontaneous recovery is expected from this injury without surgical intervention.

Management of Neural Discontinuity

In cases of complete facial nerve disruption, reestablishment of direct nerve continuity is required for restoration of muscle function. Reapproximation of freshened edges must be accomplished without placing tension across the suture line, through simple epineurial sutures. When injury occurs within the temporal bone, thorough exposure of the site of injury is recommended, and surgical repair is indicated when 50% of the diameter of the facial nerve appears to have been violated (3).

After facial nerve injury or sacrifice, if a tensionless neurorrhaphy is not possible because of a gap between the cut edges, then a nerve graft is employed to bridge the

neural defect. In facial nerve reconstruction, the three most commonly employed nerve grafts are the great auricular nerve, the sural nerve, and the medial antebrachial cutaneous nerve (Fig. 178.1). For short nerve gaps in the absence of head and neck malignancy, the great auricular nerve is a convenient choice. This often does not require a separate incision from the primary facial nerve exposure incision. The resulting anesthesia to the ipsilateral auricle is well tolerated, and the nerve is of adequate diameter and caliber to provide a suitable graft. However, for nerve gaps of greater than 10 cm, the great auricular nerve does not always provide sufficient length, and the sural nerve becomes a better option. The nerve is removed from the leg via a short incision adjacent to the lateral malleolus and can be harvested through a series of stair-step incisions, a minimally invasive stripping technique, using endoscopic equipment (Fig. 178.2). The resulting segment of anesthetic skin on the dorsum of the foot does not pose a significant clinical problem, and the nerve can yield up to 30 cm in length. For total facial nerve reconstruction from the main trunk to the peripheral branches, the medial antebrachial cutaneous nerve is most appropriate. There are at least four reliable branches, and it provides adequate length to graft the entire facial nerve, from the geniculate ganglion to the medial border of the parotid gland.

For both primary nerve repair and nerve grafting, surgery should be performed within the first 72 hours after injury or sacrifice, irrespective of the need for subsequent

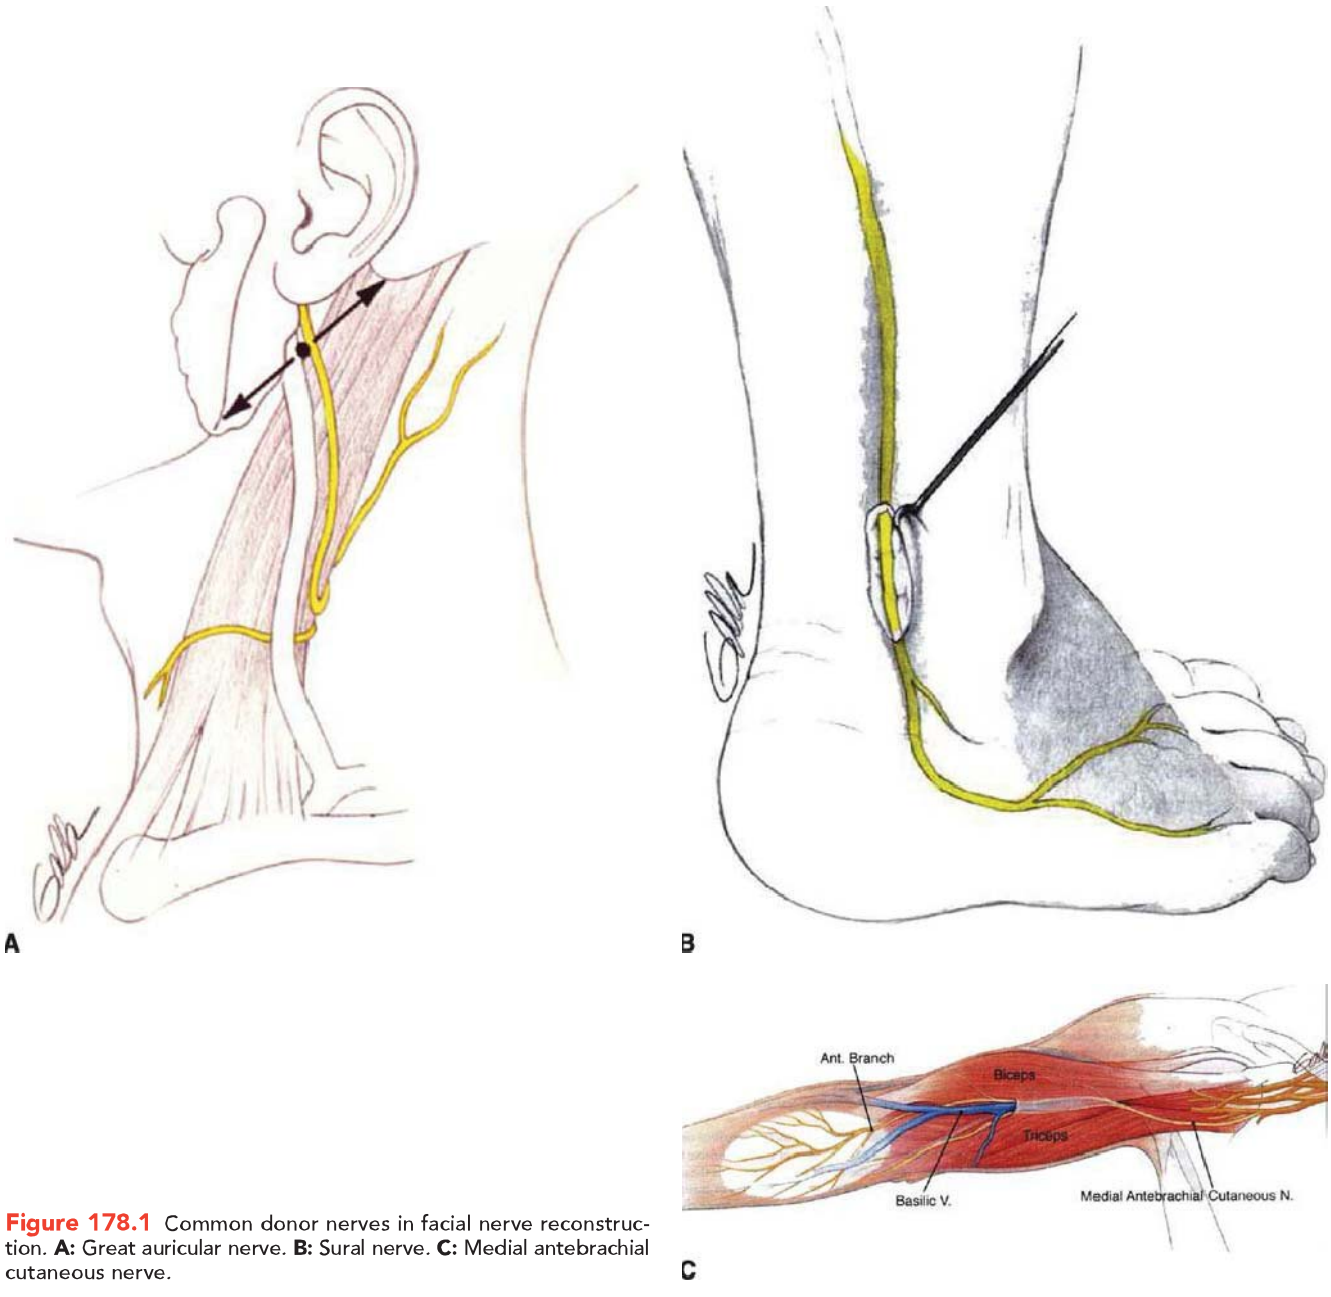

Figure 178.1 Common donor nerves in facial nerve reconstruction. **A:** Great auricular nerve. **B:** Sural nerve. **C:** Medial antebrachial cutaneous nerve.

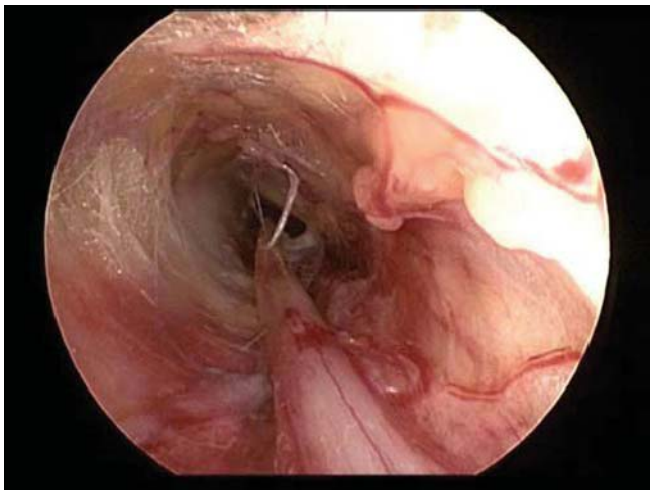

Figure 178.2 Endoscopic view of sural nerve during harvest. Note the nerve at the 6 o'clock position.

radiation therapy (4). During this time frame, the distal nerve segments retain electrical stimulability, making identification easier. Meticulous debridement and careful microsurgical technique are of paramount importance in optimizing outcome. There is debate as to the best method of nerve coaptation, as it applies to both primary and graft repair. Epineurial repair has been contrasted to fascicular repair, though no study has convincingly demonstrated improved regenerative outcome based upon fascicular facial nerve repair. Therefore, given its relative simplicity, the current standard is to perform epineurial suture repair. Though not fully established as more efficacious, it is now becoming commonplace to further reinforce the repair using fibrin glue stabilization (5).

Reinnervation Techniques

When the reestablishment of neural continuity is not possible based upon absence of an adequate proximal facial nerve stump at the brainstem, or severe comminution within the temporal bone, an alternative approach to restoring neural input to the facial musculature involves nerve substitution. This approach, also termed reinnervation, involves performing surgery to deliver neural input to the distal facial nerve and musculature via an alternative motor nerve. The hypoglossal facial transfer is most often used, though investigators have studied the utility of the spinal accessory nerve, the motor branch to the sternocleidomastoid muscle, and the masseteric branch of the trigeminal nerve as alternative inputs for the distal facial trunk. Axonal ingrowth through the distal facial nerve to the target muscles provides resting tone to the facial musculature, and voluntary movement of the tongue, shoulder, or muscle of mastication elicits facial movement. Reinnervation techniques are most commonly employed following skull base tumor resection, when the facial nerve is sacrificed at the brainstem, or when the facial nerve is not actually sacrificed but does not appear to be reaching facial muscle targets after a 12-month waiting period, based upon clinical examination and electrophysiologic studies.

The advantages of the hypoglossal nerve as a donor for reinnervation techniques include its location, close to the extratemporal facial nerve; its dense population of motor axons; and the relative acceptability of the resultant hemitongue weakness. In the classic XII-VII transfer, the entire hypoglossal nerve is transected and reflected superiorly, and a neurorrhaphy to the facial nerve stump is performed (Fig. 178.3A). Several modifications have been described (6) (Fig. 178.3B–D), including the "split" XII-VII transfer, where approximately 30% of the width of the hypoglossal nerve is divided from the main trunk of the nerve for several centimeters, and secured to the lower division of the facial nerve (Fig. 178.3B). Another modification is the XII-VII jump graft, designed to reduce tongue morbidity by avoiding the splicing away of a significant length of the hypoglossal trunk. This involves an end-to-side neurorrhaphy between the hypoglossal nerve and a donor cable graft (usually the great auricular nerve), which in turn is sewn to the distal facial trunk (9) (Fig. 178.3C). This modification evolved from a more precise appreciation of the microanatomy of the hypoglossal nerve, which demonstrates interwoven fascicular architecture; separating a 30% segment away from the main trunk for several centimeters divides a significantly greater number of axons than if the fibers were oriented in parallel.

In circumstances where the facial nerve can be mobilized within the temporal bone and reflected inferiorly, removal of the mastoid tip has permitted direct coaptation of the facial nerve to the hypoglossal nerve, without the need for an interposition graft (see Fig. 178.3D). Elimination of the cable graft provides a theoretical regenerative advantage by reducing from two neurorrhaphies to one.

Surgical Technique

The classic XII-VII procedure is performed via a modified Blair parotidectomy incision. The main trunk of the facial nerve and the pes anserinus are identified using standard facial nerve landmarks. The hypoglossal nerve is identified deep to the posterior belly of the digastric muscle and is followed anteriorly, to just beyond the branching of the descendens hypoglossi. The hypoglossal nerve is sharply transected and reflected superiorly to meet the facial nerve. The facial nerve is transected at the stylomastoid foramen, reflected inferiorly, and secured to the hypoglossal nerve with several 10-0 nylon epineurial microsutures.

The split XII-VII transfer (Fig. 178.3B) provides many fewer axons and is therefore best utilized only for the lower segment of the face. In the jump graft procedure (Fig. 178.3C), the great auricular nerve graft is harvested and interposed between the hypoglossal nerve and the facial stump. For the facial nerve mobilization out of the

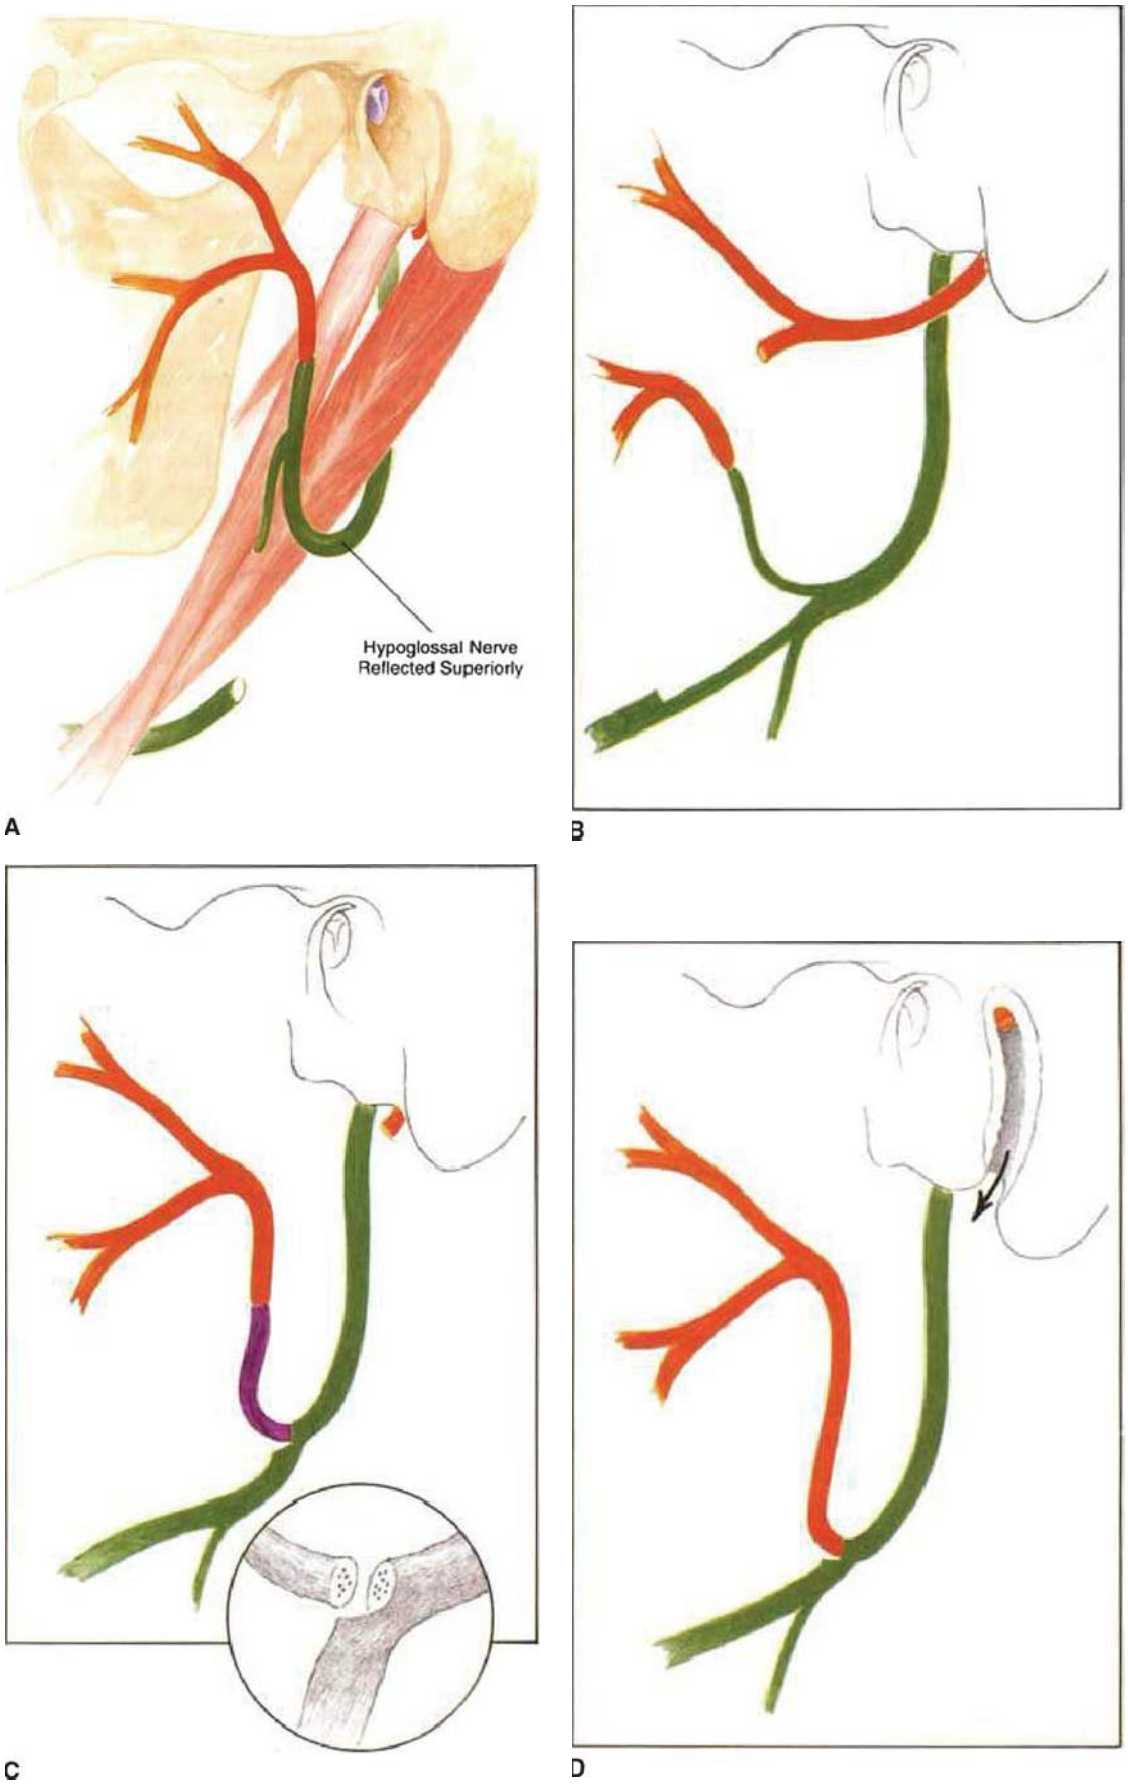

Figure 178.3 Hypoglossal facial nerve transfer. Hypoglossal nerve is shown in *green*, facial nerve in *orange*. **A:** Classic procedure, with entire hypoglossal nerve transected. **B:** Modification with 40% segment of nerve secured to lower division. **C:** Jump graft (*purple*) modification. Insert shows how graft is positioned to capture axons extending from the proximal aspect of the opened hypoglossal nerve. **D:** Reflection of the facial nerve out of the mastoid bone to meet the hypoglossal nerve in the neck.

temporal bone, the proximal facial nerve is mobilized from the temporal bone via mastoidectomy approach, sectioned at the second genu, and transposed into the neck by removal of the mastoid tip. The facial nerve can be further mobilized by dissecting it away from the parotid tissue beyond its bifurcation. The end-to-side neurorrhaphy is executed by removing a segment of hypoglossal epineurium, then cutting a 30% opening into the hypoglossal nerve and allowing exposure of the severed axons.

With a XII-VII transfer, good resting facial tone is achieved in over 90% of patients. When successful, the transfer allows deliberate facial movement with intentional manipulation of the tongue. Results are variable, and it is generally agreed that reinnervation must be performed within 2 years following injury, before facial muscle fibrosis and atrophy progress to a point where meaningful tone and movement are not achievable.

Two significant drawbacks of the procedure are the mass facial movement experienced by many patients and the variable tongue dysfunction, which has been categorized as "severe" in up to 25% of patients. Articulation and mastication difficulties are commonly cited. The modifications mentioned above are aimed at one or the other of these two problems. The procedure is contraindicated in patients who are likely to develop other cranial neuropathies (i.e., neurofibromatosis type II) or who have ipsilateral tenth nerve deficits, as the combined X-XII deficit can result in profound swallowing dysfunction.

VII-VII Cross-Face Grafting

Some have advocated utilizing branches of the contralateral facial nerve to drive the denervated facial musculature. It is the only donor source with the potential for mimetic function (the involuntary blink and emotive smile), and it is significantly arborized distally, so several branches may be sacrificed for use in cross-facial grafting, without adversely affecting the healthy side. Donor branches contain many fewer motor axons than the hypoglossal to power the paralyzed side, so the motor input provided by the hypoglossal nerve is distinctly superior. The use of the contralateral facial nerve strictly for reinnervation of native facial musculature has largely been replaced by cross-face nerve grafting in conjunction with free muscle transfer.

ZONAL APPROACH TO THE PARALYZED FACE

The goal of modern facial reanimation surgery is to address each specific functional and aesthetic zone of the face during the rehabilitation process (1). In order to identify specific zonal deficits, it is helpful to divide the face into upper, middle, and lower facial zones and to systematically characterize each of the issues that arise within those zones. Then, the choice as to whether to pursue a static correction of position of facial landmarks, a dynamic reconstruction that introduces movement, or alternative reanimation techniques can be made separately for each area. Below, we present approaches to each zone of the face, based upon location and functional issue.

The Upper Facial Zone

The three key regions in the paralyzed upper face are the brow, the upper eyelid, and the lower eyelid. In facial nerve dysfunction, the brow is most commonly ptotic, though it can also be in a balanced position, or be paradoxically hyperelevated. Significant brow ptosis can seriously impair peripheral vision. The upper eyelid can be superiorly malpositioned, from both paralysis of the orbicularis oculi and foreshortening of the levator palpebrae superioris (LPS) based upon the lack of periodic passive stretching of the muscle from the orbicularis oculi. The lack of passive stretch results in inappropriate cross-linking of the LPS myosin bridges, resulting in foreshortening. In chronic synkinesis (i.e., after viral facial paralysis or skull base surgery), the upper lid can also be inferiorly malpositioned and can be accompanied by acquired ptosis, likely from disinsertion of the tendon of the LPS under the chronic influence of the hyperkinetic orbicularis oculi. The flaccid lower eyelid can fall away from the globe, producing both scleral show and ectropion. Synkinesis results in superior malposition of the lower lid, with a slit-like palpebral fissure. Hyperlacrimation with eating, termed the syndrome of crocodile tears, or Bogorad syndrome, must also be assessed.

Based upon analysis of the upper facial issues, a management plan is designed. Usually, the brow and upper lid are addressed surgically, even when recovery through a graft is expected. Surgical management of the lower lid may be reserved for cases in which permanent flaccidity is clinically apparent.

Surgical Techniques

For the inferiorly positioned brow, surgical correction is ordinarily performed in the office setting. The brow can be secured into its proper position either by performing subperiosteal dissection followed by soft tissue fixation using biodegradable polymeric devices (Endotine Inc., Coapt, Palo Alto, CA) or by using suture-bearing bone pins. Additional options for brow ptosis correction include direct brow lifting and midforehead brow lifting. Alternatively, a two-stitch subcutaneous brow lift can be executed (Fig. 178.4). Using either surgical approach, excellent correction of brow position can be achieved. Recurrent brow ptosis may occur and is usually amenable to office revision.

The Upper Eyelid

There are three approaches to the flaccidly paralyzed upper eyelid: eyelid-weighting techniques, eyelid spring placement, and tarsorrhaphy. The most common and

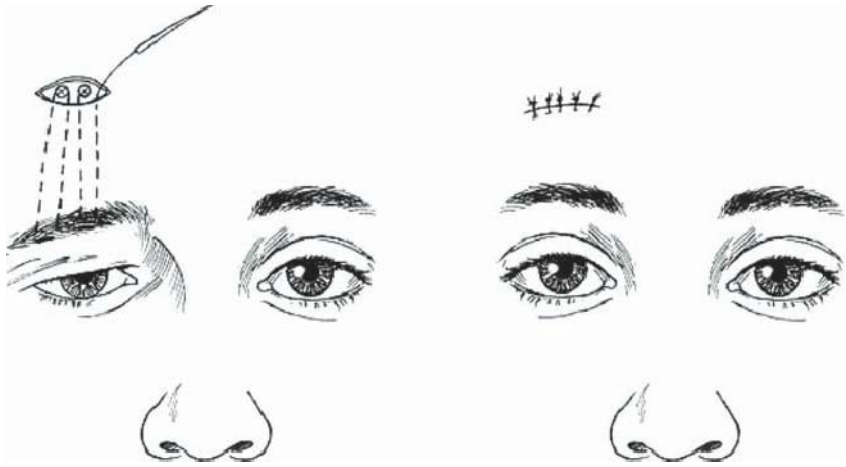

Figure 178.4 Suture-based brow lifting technique, showing placement of sutures from brow to bone pins.

predictable of these approaches is placement of a weighted implant, made of either gold or platinum. The thin profile platinum weight is preferred (7), given its higher density and the lack of reported allergic reactions, which occur up to 9% of the time using gold. The thin implants are barely visible beneath the skin, compared with thicker gold implants; the technique is straightforward and is performed under straight local anesthesia. An incision is made in the supratarsal crease, and a plane is developed deep to the orbicularis oculi, exposing the anterior surface of the tarsal plate. The implant is inserted and centered over the medial limbus. It is secured with permanent 6-0 clear nylon sutures to the tarsal plate (Fig. 178.5). If sufficient recovery to protect the cornea does occur through a nerve graft or via reinnervation, the eyelid weight is easily removed.

Eyelid springs are designed to achieve a more natural blink. However, the procedure carries a high revision rate, nearly 100%, and therefore lacks the reliability of the eyelid-weighting techniques. Tarsorrhaphy techniques (Fig. 178.6) are extremely effective at protecting the cornea but yield the least favorable aesthetic result.

For the hypertonic, inferiorly positioned upper lid seen in ocular synkinesis, lateral canthal botulinum toxin administration is effective in resolving hyperkinesis, improving quality of life, and restoring a normal palpebral fissure width (Fig. 178.7) (8). This approach involves serial treatments at 4- to 6-month intervals.

The Lower Eyelid

The weak lower eyelid may be addressed using tarsal strip procedures, in which a small segment of the lateral tarsus is removed to tighten the lower lid, though this may not have the desired long-term effect in the paralyzed eye. More long-lasting approaches include placement of a fascia lata sling from the nasal bone medially, through the lower eyelid on the lower tarsal plate, to the superolateral orbital rim (Fig. 178.8). The surgical technique involves harvesting fascia lata from the thigh and the creation of a 0.5-cm × 10-cm strip. The fascia is secured to the nasal bone via a single bone anchor and tunneled subcutaneously with the use of a fascia needle. A small nick is made in the lateral brow, to expose a segment of the superolateral orbital rim. A through and through hole is drilled in the lateral orbital rim with a 1.5-mm otologic drill, and a suture is passed through the fascia lata and through the bone. This provides a "seat belt" for the lower lid, and tension can be very precisely set on the lower lid to achieve the proper location. This procedure provides good long-term results; however, the surgical technique possesses a steep learning curve.

Lacrimal Function

Facial nerve damage proximal to the geniculate ganglion can result in inappropriate tearing during salivation, where fibers intended for the salivary glands are misrouted to the lacrimal gland. This phenomenon is known as Bogorad syndrome (synonymous with the syndrome of crocodile tears). Hyperlacrimation with eating can be managed with botulinum toxin injection into the lacrimal gland (9). Occasionally, there is normal tear volume that masquerades as hyperlacrimation, based upon failure of the punctal system to adequately drain the fornix. Dacryocystorhinostomy, lower lid correction, and good lid hygiene can ameliorate this condition. Hypolacrimation is treated with periodic administration of artificial tears.

The Middle Facial Zone

Functional and aesthetic issues that arise in the midface include nasal base malrotation, leading to external nasal valve collapse, malposition of the nasolabial fold (NLF) (either hyperprominence or effacement), upper lip ptosis, philtral deviation, and poor excursion of the oral commissure (1). Hypertonic facial paresis, such as that seen following poorly recovered Bell palsy or Ramsay Hunt syndrome, generally leads to an overprominence of the nasolabial fold.

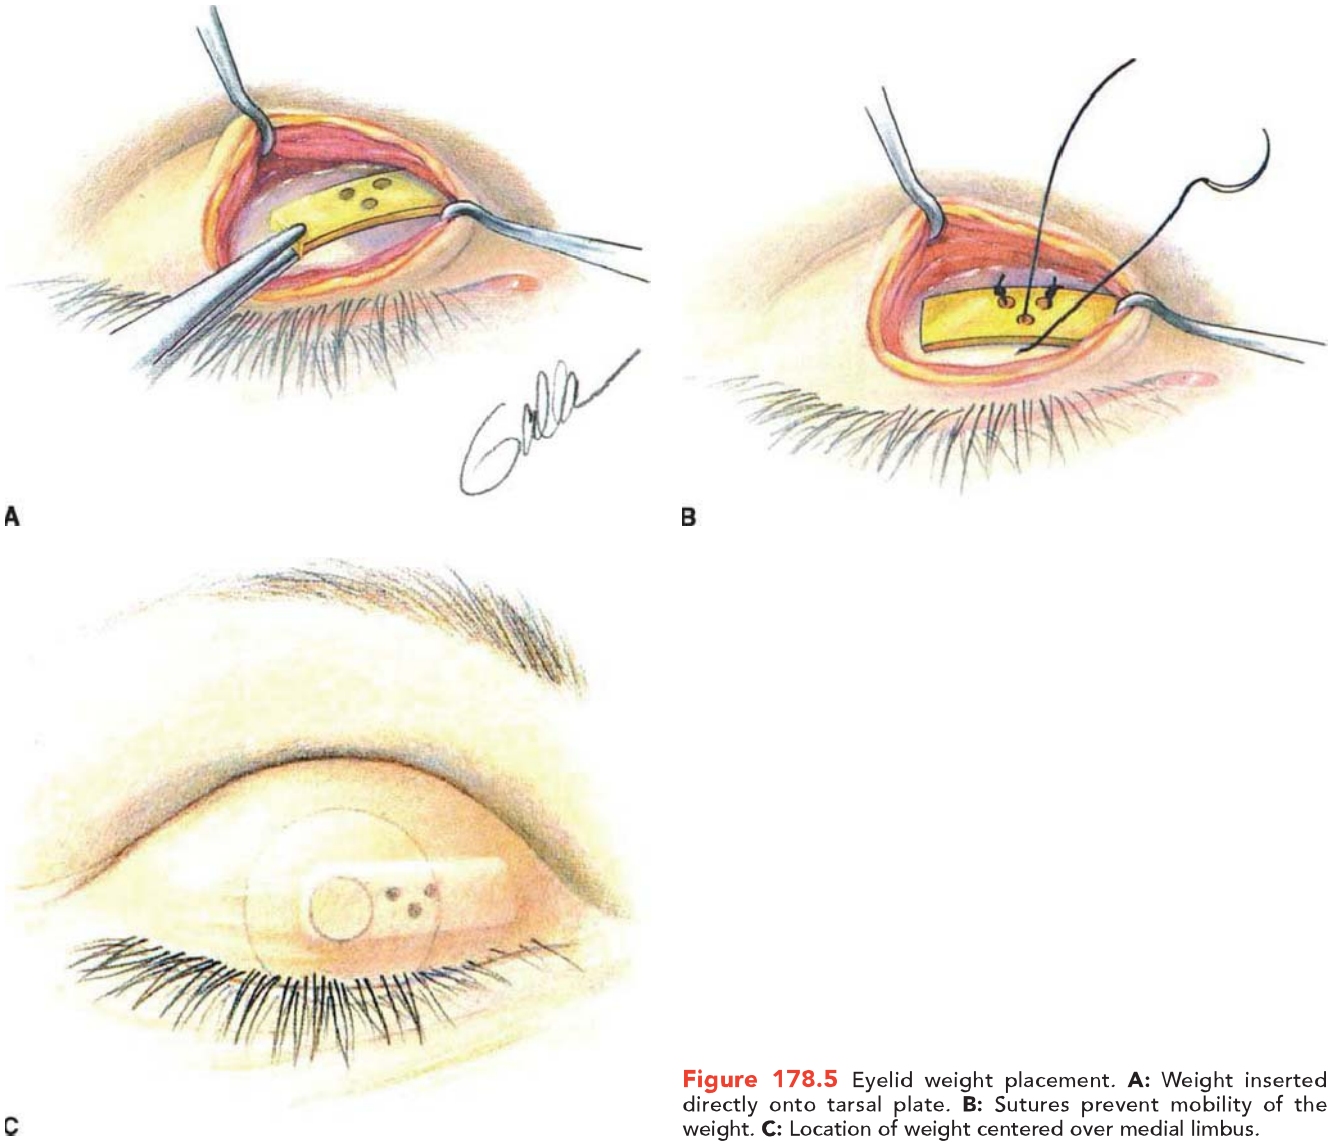

Figure 178.5 Eyelid weight placement. **A:** Weight inserted directly onto tarsal plate. **B:** Sutures prevent mobility of the weight. **C:** Location of weight centered over medial limbus.

Surgical Techniques

The Nose

External nasal valve collapse is addressed with a fascia lata sling technique (10). A segment of fascia lata is harvested from the lateral thigh and tunneled subcutaneously from a temporal and preauricular incision to an incision made in the alar crease. The fascia lata is secured medially to the sesamoid cartilages in the nasal ala and laterally to the true temporalis fascia (Fig. 178.9). Additional lower lateral cartilage batten grafting may help in cases of persistent valve collapse due to lower lateral cartilage in-bowing during inspiration.

The Nasolabial Fold

Nasolabial fold abnormalities are addressed according to whether there is flaccid or hypertonic facial paralysis. Suture suspension techniques analogous to those used during face lifting are placed either medial to the fold (to define an effaced NLF) or lateral to the fold (to soften a hyperprominent NLF) (1).

Botulinum toxin chemodenervation in the midface is not helpful for nasolabial fold hyperprominence, as it frequently results in upper lip ptosis without correcting the asymmetry.

The Oral Commissure and Smile

Restoration of the smile is one of the most important goals of the facial reanimation surgeon. While every individual possesses a slightly different smile, there are three basic smile shapes (11), which are classified depending upon which muscle groups dominate during smiling (Fig. 178.10). Sixty-seven percent of individuals possess a "zygomaticus major" smile, in which the zygomaticus muscles and buccinator muscle have the strongest action during emotive smiling. In 30% of individuals, the zygomaticus and levator labii superioris muscles codominate, giving a

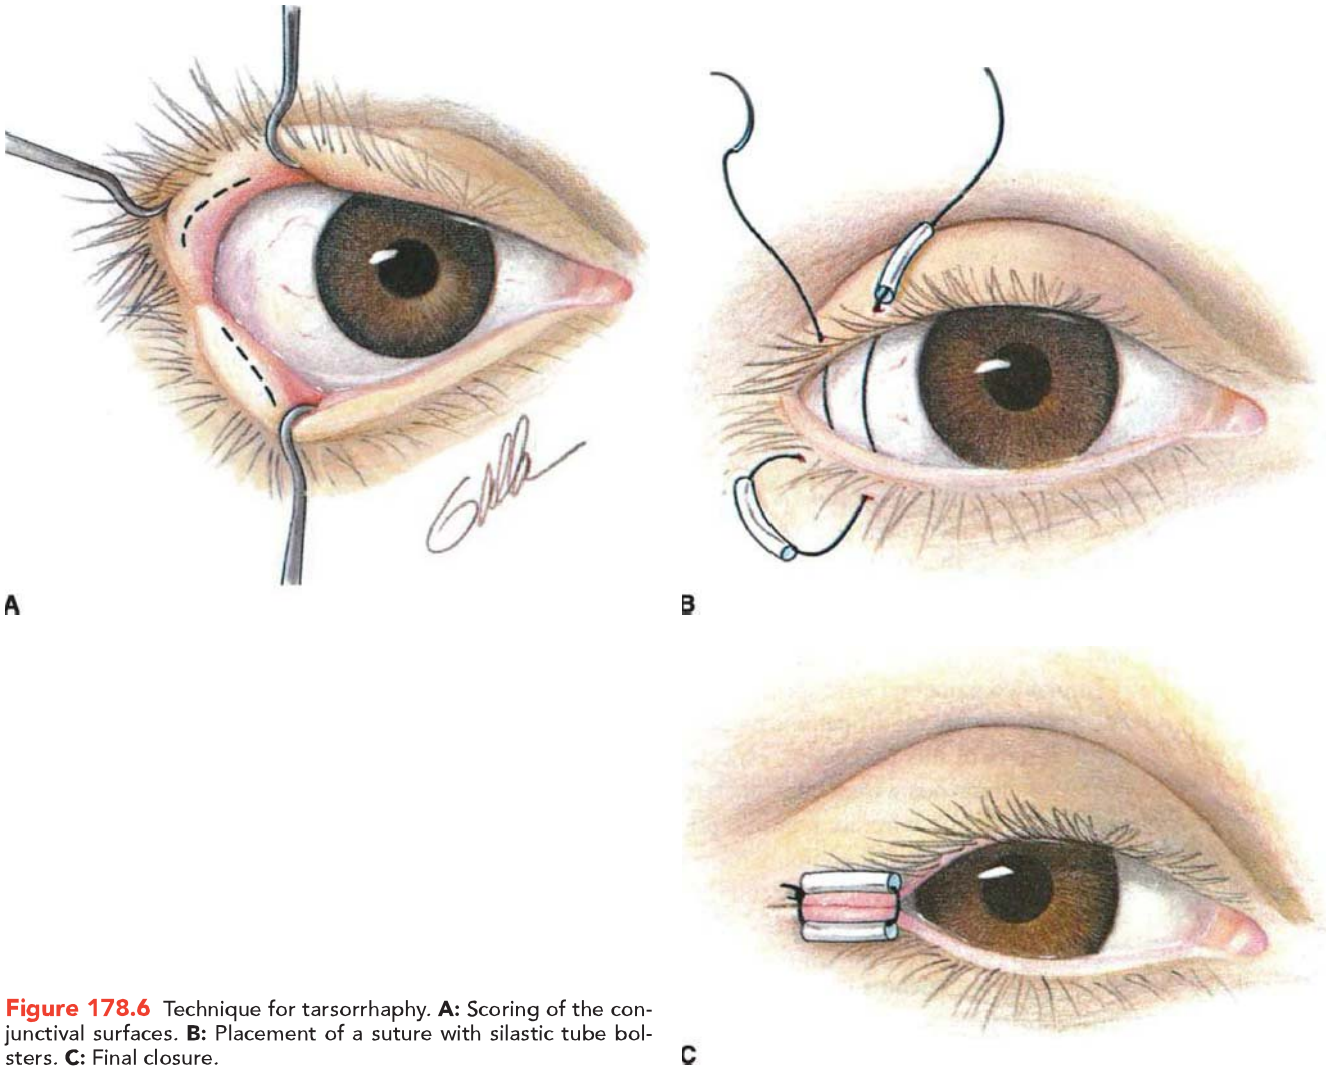

Figure 178.6 Technique for tarsorrhaphy. **A:** Scoring of the conjunctival surfaces. **B:** Placement of a suture with silastic tube bolsters. **C:** Final closure.

"canine" smile. The most infrequently encountered smile type is the "full-denture" smile, occurring in 2% of the population and characterized by equal action of both the lip elevators and depressors. It is important in patients with unilateral paralysis to observe which smile type is present, so that reconstructive efforts can most closely match the unaffected side.

Options for reanimation of the midface and oral commissure include regional or free muscle transfer for dynamic reanimation or fascia lata suspension for static reanimation. Ordinarily, static suspension is reserved for patients with a poor prognosis, in whom regional muscle transfer is not a practical option, or dynamic reanimation failures. For regional muscle, the temporalis, masseter, and digastric muscles have been utilized, but in the past decade nearly all reanimation surgeons have abandoned the use of the masseter muscle, based upon its unfavorable vector pull and the significant contour defect it leaves. The temporalis muscle is the mainstay of regional muscle transfer, based upon its surgical simplicity and its fan-shaped architecture, permitting precise vector matching with the individual's native smile type.

Temporalis Transfer

The procedure is performed through an incision from the superior temporal line down to the attachment point of the lobule and may extend several cm below the angle of the mandible. There are two contemporary approaches to transferring the muscle. The first approach involves elevating the temporoparietal fascia off the superficial surface of the temporalis muscle, on its vascular pedicle, and rotating it posteriorly to reveal the muscle. A 1.5-cm strip of the muscle is elevated off the calvarium to the level of the zygomatic arch and reflected over the arch to reach the modiolus. The second approach, emerging in popularity in the past several years, is to expose the temporalis tendon as it attaches to the coronoid process and to remove it from the bone and secure it to the modiolus. This can be performed through a lateral incision (as above) or through a nasolabial crease incision, or intraorally.

Figure 178.7 Management of periocular synkinesis with botulinum toxin. **Top:** Pretreatment view of eye while smiling. **Bottom:** Posttreatment view of same. Note more close matching of the palpebral fissure to the normal side.

Potential problems arising after temporalis muscle transfer include a visible bulge overlying the zygomatic arch (when using the first method described above), excess midfacial bulk, hollowing and/or alopecia in the temporalis fossa, and inadequate excursion of the transferred muscle. These problems can be largely avoided with meticulous surgical technique and proper candidate selection. Edentulous patients who are likely to have disuse atrophy of the muscle and those with preoperative wasting or trigeminal dysfunction are not good surgical candidates.

Free Muscle Transfer

Patients under the age of 70, in whom life expectancy is greater than 2 years, make good candidates for free muscle transfer. The most important advantage of this approach is that when it is driven by a cross-face nerve graft, it has the potential to yield an involuntary, emotive smile, and excursion is often greater than that seen using temporalis transfer. Because this approach involves microvascular anastomoses, and sometimes requires multiple operations, patients with vascular disease or other significant comorbidities are not appropriate candidates. Free muscle can alternatively be driven by the ipsilateral motor branch to the masseter muscle as a single-stage operation, which results in higher success rates and greater excursion but does not provide a completely involuntary, spontaneous emotive smile.

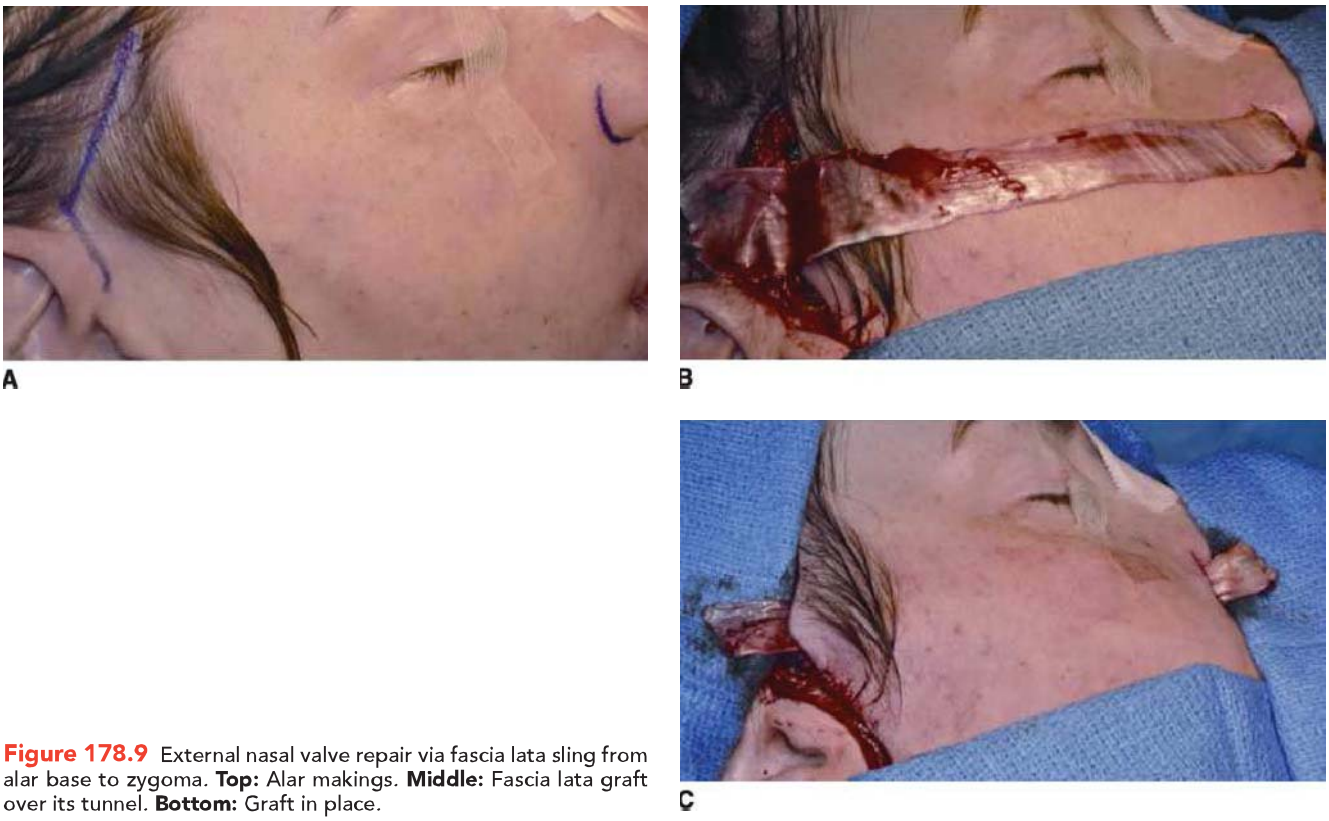

Figure 178.9 External nasal valve repair via fascia lata sling from alar base to zygoma. **Top:** Alar makings. **Middle:** Fascia lata graft over its tunnel. **Bottom:** Graft in place.

First-Stage Cross-Face Nerve Grafting

A preauricular incision is made on the nonparalyzed side, and a flap is raised on the parotidomasseteric fascia to the anterior border of the parotid gland. Dissection within the masseter fascia is carried out to identify several facial nerve branches. The branches yielding isolated smile movement are selected as the donor branches and transected sharply. A sural nerve graft is harvested from the leg and tunneled subcutaneously from the donor branches, across the upper lip, to the gingivobuccal sulcus on the paralyzed side, where the tip of the graft is marked with a 4-0 nylon suture. Nerve coaptation is performed between the sural nerve and the donor facial nerve branches, using 10-0 nylon sutures (Fig. 178.11). The penetration of axons into the graft is followed clinically by tapping on the graft (the Tinel sign); tingling in the zygomaticus muscle groups on the donor side indicates the presence of regenerating axons. Ordinarily, second-stage free muscle transfer ensues 6 to 9 months later.

Free Muscle Transfer

The gracilis muscle was the first muscle utilized in successful facial reanimation (12) and remains the most popular choice for this purpose, though pectoralis minor and latissimus dorsi are favored by some centers.

The gracilis muscle is harvested from the medial aspect of the thigh. An incision is made 1.5 cm posterior and parallel to a line connecting the pubic tubercle to the medial condyle of the tibia. The belly of the gracilis muscle is identified, and the vascular pedicle is located entering the deep surface of the muscle, 8 to 10 cm distal to the pubic tubercle. The obturator nerve is then identified 2 to 3 cm proximal to the vascular pedicle and similarly traced. The flap is harvested, and the length of muscle required is determined by measuring the distance from the oral commissure to the tragus and adding 2 cm. Thus, upon inset, resting length of the muscle is reestablished.

For facial inset, a preauricular incision is made and extended to just below the mandible, and the facial vessels are prepared for microvascular anastomosis. A thick skin flap is raised, extending medially to expose the orbicularis oris. In the two-stage procedure, the stump of the cross-face nerve graft is identified in the gingivobuccal sulcus for the neurorrhaphy, and in the single-stage procedure, the masseteric nerve is identified by dividing masseter fibers off the zygomatic arch to expose the nerve on the deep muscle surface. The gracilis muscle is then secured to the modiolus, stretched to its resting tension length, and secured to the temporalis fascia in the appropriate vector, taking into account the patient's healthy side smile vector. The microvascular anastomoses and the neurorrhaphy are performed, and the incisions are closed over suction drainage (Fig. 178.12).

Movement is expected starting approximately 3 months after transferring a trigeminally driven muscle and 8 to 10 months following cross-face nerve graft–driven muscle transfer (Fig. 178.13). Drawbacks include excessive

midfacial bulk and the 8% to 30% failure rate, universally cited among those who perform this operation routinely. Failure is thought to occur secondary to poor ingrowth of the donor nerve fibers into the transferred muscle. Less commonly, microvascular failure or improper resting

tension of the muscle may result in an unsatisfactory outcome.

The Lower Facial Zone

Within the lower face, the lower lip, the chin, and the neck require independent assessment. The lower lip tends to be superiorly displaced, based upon lack of tone from the depressor anguli oris and the depressor labii inferioris. In hypertonic facial paralysis, there may be significant hypertonicity in the mentalis muscle and the platysma, which leads to chin puckering and excessive downturning of the corner of the mouth (Fig. 178.14). Lower lip displacement can be managed by contralateral lower lip weakening techniques, which would include either chemodenervation with botulinum toxin (Fig. 178.15) or transection of fibers of the contralateral depressor labii inferioris (13). Dynamic reanimation to the affected lower lip has been described, using digastric muscle transfer, and several surgeons have described the utility of free platysma transfer to the lower lip, though the high success rate of contralateral lower lip weakening has diminished the focus on dynamic lower lip techniques.

Mentalis dimpling is effectively managed with chemodenervation therapy, and platysmal synkinesis is eliminated either using botulinum toxin or via office-based platysmectomy (Fig. 178.16) (14).

SUMMARY

Rehabilitation of the paralyzed face is a challenging medical, surgical, and physical therapy problem. The management strategies are determined by many critical variables, and a systematic approach to the problem is absolutely mandatory. Careful evaluation of each of the different facial zones will provide the best, most all-encompassing plan for each individual patient. In addition to surgical intervention, there is a critical role for both directed physical therapy and botulinum toxin chemodenervation (8,9,15). These adjuncts are relevant in the acutely paralyzed face (brow and lower lip), as well as the hypertonic, synkinetic face (lacrimal gland, orbicularis oculi, mentalis, and platysma). Management via a team approach, which includes neuro-otologists, facial plastic surgeons, head and neck surgical oncologists, oculoplastic surgeons, and physical therapists together, will optimize the outcome.

HIGHLIGHTS

- Facial paralysis has significant functional, aesthetic, and communication consequences.
- Nerve injuries are classified using the Sunderland scale according to severity, and neural discontinuity is managed with timely primary repair or nerve grafting.
- Hypoglossal–facial transfer provides global input to the facial musculature when there is no proximal facial nerve stump for grafting.
- Smile reanimation is accomplished using either free or regional muscle, and results achievable can match the excursion of normal smiling.
- Physical therapy, botulinum toxin chemodenervation, and office adjunct procedures play a critical role in thorough management of facial paralysis.

Surgical Anatomy of the Nose: A Foundation for Rhinoplasty

179

David W. Kim *Ted Mau*

GENERAL PRINCIPLES

Success in rhinoplasty depends on the surgeon's ability to create favorable functional and cosmetic changes to the nose. The operation is difficult for a number of reasons: noses are complex, three-dimensional, highly variable structures; most maneuvers attempt to alter a framework that has inherent resistance to manipulation; and the changes that are created are often subtle and subject to relentless postoperative forces of scar contracture. To overcome these challenges, the surgeon must have the ability to analyze a nose and match its variations to underlying structural correlates. Techniques may then be chosen to alter these structures into an optimal form while maintaining support and function. Finally, the maneuvers must be executed with meticulous precision. In rhinoplasty, these steps of diagnosis, selection of technique, and execution are possible only with a clear understanding of the complex anatomy.

This chapter describes sequentially the anatomy of the different regions and components of the nose. Infinite variations of these regions exist and may be the result of differences in ethnicity, gender, age, trauma, congenital deformity, or prior surgery. The unique structural characteristics of each nose underlie each individual's external appearance and may motivate that person to seek surgery. Whether or not these variations should be classified as variant anatomy is a semantic question, but because of this huge diversity, it is problematic to designate a "normal" archetypal anatomy toward which rhinoplasty surgery should aspire.

Each section in this chapter begins with general anatomic concepts, detailing the orientations and relations that are most commonly encountered. Subsequently, "variations" from normal anatomy are discussed, particularly as they pertain to rhinoplasty. A separate section focuses on the structural architecture of the nose, emphasizing how the various individual anatomic elements integrate into a stable unit. Although the chapter emphasizes anatomy predominantly, discussions on rhinoplasty philosophy, analysis, technique, and complications are included where germane.

SURFACE ANATOMY

Discussion of the surface anatomy of the nose begins within the larger contextual framework of the face. In general, the nose occupies the central horizontal third of the face, from the glabella to the subnasale, and central vertical fifth, between the medial canthi. Variations of nasal dimension and position may cause the nose to extend outside of these confines. These divergences may draw attention to the nose and may therefore be a patient's motivation to undergo rhinoplasty. Directional references and topographic landmarks are illustrated in Figures 179.1 through 179.5.

Subunits

The external topography of the nose is divided into six subunits. These consist of the nasal dorsum, sidewalls, tip, columella, ala/sill, and soft triangles (Fig. 179.6). These areas are defined by the shadows and highlights cast by incident light. Human visual processing depends on these light–dark contrasts to form a perception of the nose. The subunits do not necessarily have sharply defined boundaries and do not mirror exactly the underlying anatomic structures. Nonetheless, it is crucial for the nasal surgeon to identify them in preoperative assessment, particularly in external nasal reconstruction. During reconstruction, effort should be made to place scars within subunit borders whenever possible, as the human eye is more apt to discern a scar that traverses across a subunit than one that outlines it. This may require a surgeon to resect and replace an entire subunit (or subunits) involved, rather

than replace only the primary defect, even if this requires removal of areas of healthy tissue. Tissue of a similar thickness, color, and consistency should be used to reconstruct these defects.

Topography

A discussion of surgical anatomy must begin with the external topography that surgery aims to alter. A detailed discussion of aesthetic facial analysis is found in Chapter 170. What follows is a limited discussion of nasal analysis and definitions of terms with specific relevance to rhinoplasty anatomy. Correlation of nasal topography to underlying structural anatomy is introduced—details of this anatomy are discussed in greater depth in subsequent sections.

On frontal view, a gentle, unbroken curve should appear from the lateral brow to the nasal tip on each side of the nose (Fig. 179.1A). These *brow–tip aesthetic lines* should follow the normal changes of nasal width: wider cephalad at the brow/nasal root transition, narrower in the middle vault, and wider again at the tip. An irregular brow–tip aesthetic line may be correlated to bony and cartilaginous vault irregularities through palpation and close inspection with a light placed above the patient to enhance shadowing. When the upper cartilaginous vault is overly narrow, the curvature of these brow–tip lines is exaggerated.

General tip shape may be determined from the frontal and base views (e.g., bulbous, deviated, wide, amorphous, asymmetrical). The unique features of tip shape are determined by the endless variations of form, dimension, and position of the lower lateral cartilages (LLCs) and surrounding structures. Inference about the thickness of the nasal skin may be made from inspection of the contour of the tip. A tip with sharp features reflects underlying structures transmitting through thin skin. A smooth, bulbous tip is likely covered by thick skin.

The base view also provides information about the shape and size of the columella, alar base, nostrils, and infratip lobule (Figs. 179.2B and 179.4). In most noses, the frontal and base views reveal a triangular shape of the nose in which the nasal base (interface of nose and face) is wider than the tip and dorsal line. The triangularity of the tip depends on the presence of an unbroken line from a narrower nasal tip to a wider nasal base. Poor structural support along this line will manifest as alar pinching or concavity of the alar margins on frontal and base views. When the base is excessively narrow or the tip overly wide, a square or trapezoidal shape instead of triangular

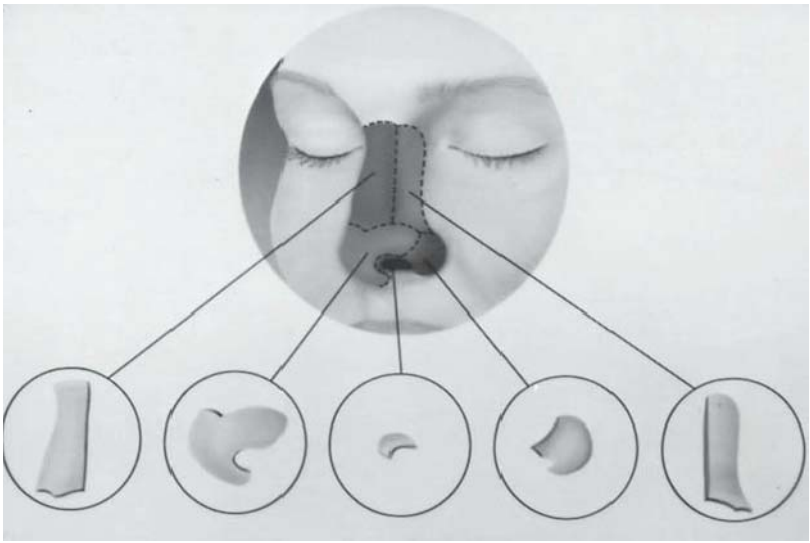

Figure 179.6 Aesthetic topographic subunits of the nasal surface. From left to right: dorsum, tip/columella, soft tissue triangle, alar lobule, and sidewall. The columella may be considered a separate distinct subunit. (From Tardy ME. *Surgical anatomy of the nose.* New York: Raven Press, 1990, with permission.)

configuration is present (1). The width of the infratip lobule reflects the underlying shape of the intermediate crura of the LLCs. Asymmetry in the columella may be caused by asymmetries of the shape or trajectory of the medial crura, deflection of the caudal edge of the cartilaginous septum, or both. The lateral flaring of the alar lobules is only indirectly determined by the shape and strength of the lateral crura of the LLCs, as the lobules themselves are composed of soft tissue only and are caudal to the lateral crura.

On lateral view, several important external landmarks may be identified (Fig. 179.2A). The nasion is the most concave point at the nasofrontal angle and corresponds anatomically to the midline of the nasofrontal suture. This angle is determined by the height of the radix, the most cephalic portion of the nasal dorsum, and the slope of the forehead. An average nasofrontal angle measures 120 degrees in the Caucasian nose. The vertical position of the nasion marks the nasal starting point and is typically between the supratarsal crease and the upper eyelid margin. The rhinion corresponds to the osseous–cartilaginous junction and often marks the location of a dorsal hump. Proceeding caudally, the presence or absence of a supratip breakpoint depends on the dorsal height of the cartilaginous septum and the projection of the domal region of the LLCs. The tip-defining point, or the pronasale, is the most anterior projection of the nose. The overall projection and rotation of the nasal tip may be assessed by using Goode's method, in which the nasal tip projection (from the alar crease to the tip-defining point) is divided by nasal length (from nasion to tip-defining point). According to Goode, the normal value should be 0.55. The nasolabial angle in men is typically between 90 and 95 degrees and in women, between 95 and 105 degrees. This angle may be affected by variations of the size and shape of the upper lip and premaxillary bone. Therefore, the nasolabial angle does not always reflect the degree of tip rotation. The lateral view of the ideal nostril is oval shaped, with 2 to 4 mm of the columella visible beneath the alar rim.

Variant Anatomy

Because the nose is a three-dimensional structure that is viewed in whole, the topographic dimensions of one area have an optical effect on the appearance of other areas. This is critical during rhinoplasty, as surgical changes to one region or parameter of the nose create the illusion of change to another. Examples as they pertain to external nasal topography follow.

Dorsal Height

The overall height of the nasal dorsum is determined predominantly by the size and development of the highly variable cartilaginous and osseous nasal septum. In general, an increased overall projection of the dorsum on the lateral view corresponds to a narrower appearance on the frontal view. Conversely, a low nasal bridge creates a wider-appearing nose from the front. This is explained by the concept that one looks down the apex of a triangle when observing a nose from the front. In a nose with a high dorsum, the sidewalls are subject to more shadowing, and the apex of the triangle appears narrower. In a nose with a low bridge, the cross-sectional triangular geometry of the nose is flattened, or if surgical hump reduction has occurred, it is truncated into a trapezoid. With less shadowing of the sidewalls, the nose appears wider on frontal view. Local differences in dorsal height create other illusions. In a normal profile, the radix, middorsum, supratip, and nasal tip are linear or nearly colinear. Because our eyes are accustomed to this norm, deviations from these relations create certain optical illusions. For instance, the presence of a mid-dorsal convexity creates an illusion of an underrotated nasal tip, irrespective of absolute tip position. A dorsal concavity, in contrast, creates a perception of increased tip rotation and a shorter nose. Before the surgeon commits to making true alterations of tip position, the effects of dorsal height and its modification must be carefully weighed.

Radix and Nasofrontal Angle

Variations in radix height have an effect on numerous aesthetic nasal parameters such as the nasal starting point, nasofrontal angle, overall dorsal profile, and apparent intercanthal distance. A low radix, as commonly seen in individuals of African or Asian descent, creates an illusion of increased intercanthal distance (see earlier explanation). If associated with tip underprojection, a low radix may create an appearance of a dorsal hump. Correction of this appearance may be accomplished with augmentation of the radix and increasing tip projection instead of reduction of the dorsum to the level of the low radix (Fig. 179.7). Maintaining a higher dorsum offers the advantages of a narrower appearance on front view and avoidance of an open-roof deformity associated with hump reduction. A high radix, in contrast, creates an appearance of decreased intercanthal distance. When excessive height at the radix blunts the nasofrontal angle, the distinction between the nose and forehead may be blurred, creating the illusion of a longer nose. This is particularly true in the presence of a posteriorly sloping forehead. Because of the abundant overlying soft tissue in this area, reduction of osseous height at the radix does not transmit well to overall profile reduction. Conversely, a more acute nasofrontal angle creates an illusion of a shorter nose, independent of the actual vertical position of the nasal starting point.

Nasolabial Angle

The nasolabial angle, formed by the upper lip and columella, is widely used as a metric for the degree of rotation of the nasal tip. This region, however, is composed of numerous anatomic components with a high degree of variation and in reality may not accurately reflect the

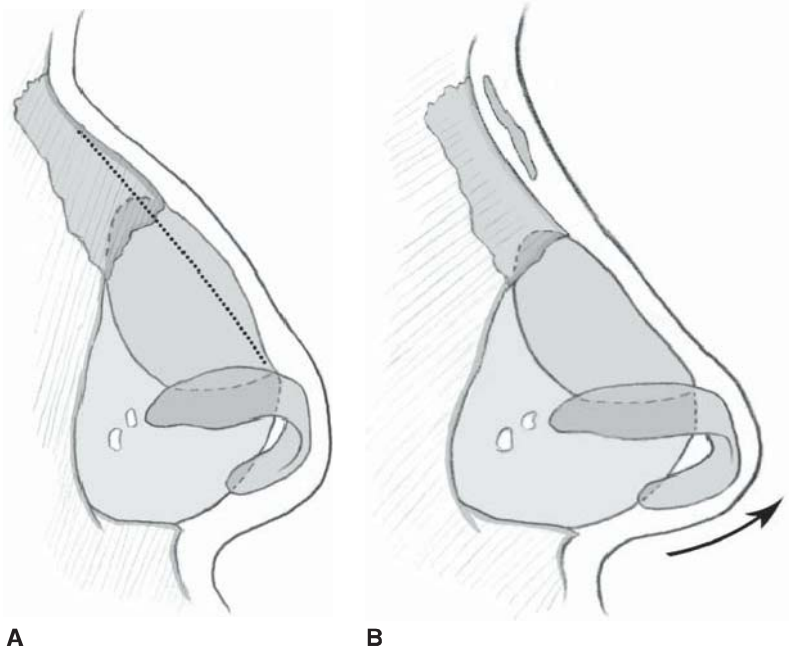

Figure 179.7 **A**: Profile view of a nose with a true dorsal hump in the region of the rhinion. Correction may involve reduction of the hump. **B**: Nose with a relative dorsal convexity due to a low radix and an underprojected nasal tip. Correction might involve elevating of the radix with a graft and increasing tip projection. Final external dorsal contour is similar in both examples.

overall degree of nasal tip rotation. Fullness in this area may be caused by an overdeveloped quadrangular cartilage in the area of the posterior septal angle, a prominent nasal spine and premaxillary bone, or tenting of the soft tissue in a projecting nose. These variations create a more obtuse angle, irrespective of the true rotational position of the nasal tip. However, even if the true rotational position of the tip is not changed, an increased nasolabial angle creates an illusion of increased tip rotation. Conversely, when these structures are less developed or retrusive, a relative deficiency on the nasolabial angle may be present, leading to a perception of counterrotation (Fig. 179.8).

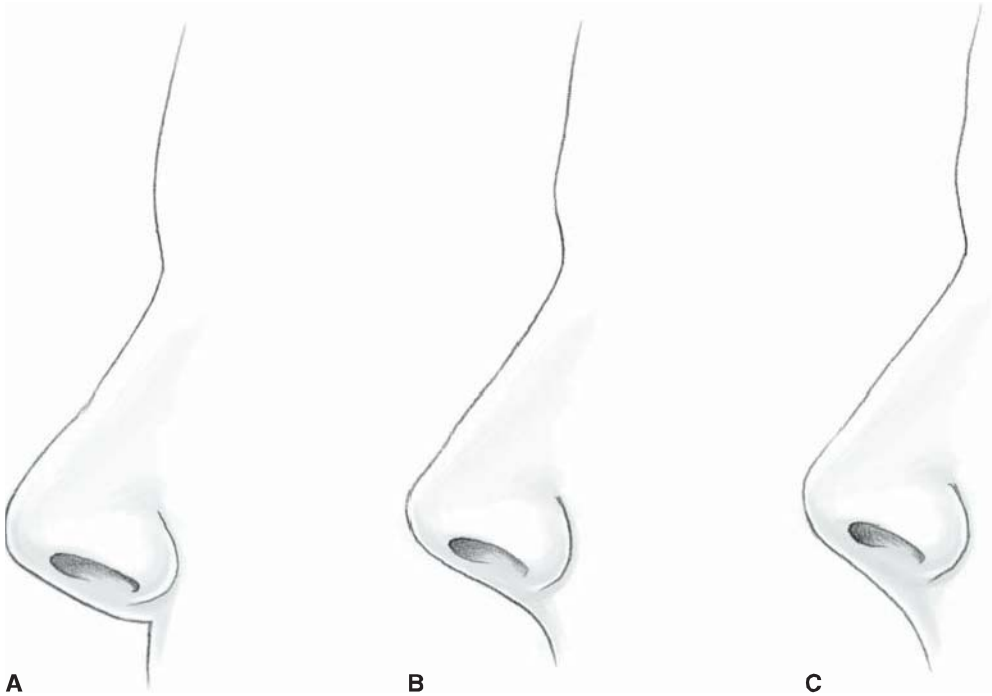

Figure 179.8 Lateral view of three noses with identical tip position. **A**: Relative deficiency of tissue at the nasolabial area and an acute nasolabial angle creates an illusion of underrotation of the tip. **B**: Nose with a moderate nasolabial angle. **C**: Fullness at the nasolabial area with an obtuse nasolabial angle creates an illusion of increased tip rotation.

Alar–Columellar Relation

With alar retraction or a dependent caudal edge of the cartilaginous septum, excessive columellar height is visible on the lateral view. This hanging columella may create an illusion of a ptotic nasal tip, even when tip position is normal. In contrast, a retracted caudal septum or a low alar margin may lead to a relative lack of columellar show and an associated illusion of increased tip rotation. The size, position, and interrelations of the medial crura, caudal septum, lateral crura, and alar soft tissue determine these variations.

SKIN–SOFT TISSUE ENVELOPE

The nose is constructed of a skeletal framework onto which a skin–soft tissue envelope (SSTE) is draped. Although the framework is the subject of most surgical techniques, the appearance of the nose is determined by the manner in which the SSTE drapes over the modified skeleton. An understanding of the composition of the SSTE and its variant anatomy guides the surgeon in choosing appropriate techniques for successful surgery.

Skin

The skin of the nose varies in thickness depending on its location. The skin is thickest at the nasion and thinnest at the rhinion (2). From the rhinion, the skin becomes progressively thicker as it descends along the dorsum to the tip, where a large number of sebaceous glands reside. The skin becomes thin again at the most caudal aspect of the nose along the alar margin and columella.

Understanding skin thickness variation along the dorsum aids the rhinoplasty surgeon in performing dorsal hump reduction. Because the skin is thinnest at the rhinion, a straight external profile requires a small relative convexity to remain in this region. If the dorsum is reduced so that a straight skeletal profile results, a slight concavity at the middorsum is likely to result after skin redraping (3). This may create a cartilaginous pollybeak, in which the supratip dorsum projects above the plane of the dorsum cephalad to it. To avoid this, hump reduction should be carried out incrementally, with verification of the effect of each pass on external contour through the SSTE.

Subcutaneous Tissue

The subcutaneous layer of the nose is made up of the superficial fatty layer, the fibromuscular layer, the deep fatty layer, and the periosteum or perichondrium. The superficial fatty layer is directly connected to the dermis. The fibromuscular layer comprises the nasal subcutaneous muscular aponeurotic system (SMAS) (4). The nasal SMAS is in continuity with the SMAS of the rest of the face and encases and interconnects the mimetic muscles of the nose. The deep fatty layer contains the neurovascular system of the soft tissue envelope. Dissection in the avascular plane between the deep fatty layer and the perichondrium and periosteum is met with little mechanical resistance or bleeding and results in the least postoperative scarring and contraction.

Muscles

The mimetic muscles of the nose reside within the SMAS. They are divided into four groups (5) (Table 179.1). The *elevator* muscles shorten the nose and dilate the nostrils, the *depressor* muscles lengthen the nose and dilate the nostrils, the *compressor* muscles lengthen the nose and narrow the nostrils, and the *minor dilator* muscles widen the nostrils. In addition to these individual functions, the muscles work synergistically to alter the shape of the nasal tip, alae, and dorsum. For example, simultaneous contraction of the levator labii superioris and the depressor septi nasi may depress the nasal tip, "round up" the supratip area, and lengthen the nose (6). The muscles, particularly the dilator naris (7), also serve to maintain the tone of the nostrils during inspiration, as illustrated in the patient with ipsilateral facial nerve paralysis with unilateral alar collapse (8). Dissection in the sub-SMAS layer of the soft tissue envelope allows the surgeon to avoid the nervous supply to the nasal muscles.

Although most rhinoplasty techniques do not directly address nasal muscles, division of the depressor septi nasi may correct drooping of the nasal tip and shortening of the upper lip during facial animation. The small, paired muscle that originates at the anterior nasal spine and inserts onto the medial crura footplates may be addressed through simple division (6), muscular release and plication (9), or dissection and transposition of the muscle (10). In selected patients, these techniques may reduce gingival show and nasal tip descent during smiling, elevate the nasal tip, and elongate the upper lip in the resting state.

Arterial Supply

The superficial vascular supply to the external nose derives from both the external and internal carotid systems. The

facial artery branches into the angular artery and the superior labial artery. The lateral nasal branch of the angular artery supplies the lateral surface of the caudal nose. Branches of the superior labial artery supply the nasal sill and the base of the columella. The columellar artery, a branch of the superior labial artery, is often encountered in the transcolumellar incision used in the external rhinoplasty approach. The septal branches of the superior labial artery enter the nose on each side of the nasal spine and form the major blood supply to the anterior septum. Large septal mucosal flaps may be pedicled on the nasal spine area with these branches for reconstructive purposes.

The dorsal nasal artery, an external branch of the ophthalmic artery, anastomoses with the lateral nasal branch of the angular artery, forming an axial arterial network for the dorsal nasal skin. Arterial supply to the nasal tip derives from branches of the anterior ethmoid and angular arteries. The external nasal branch of the anterior ethmoid artery perforates the transverse nasalis muscle of the nasal sidewall and descends toward the nasal tip. The lateral nasal branch of the angular artery sends off branches from the ala anteriorly toward the nasal tip. The vascular plexus to which these arteries contribute resides predominantly in the adipose layer just deep to the SMAS. Remaining in the plane just above the perichondrium and periosteum during dissection minimizes injury to these vessels.

Sensory Nerve Supply

Sensation to the external nasal skin is supplied by branches of the ophthalmic and maxillary divisions of the trigeminal nerve. Twigs from the supratrochlear and infratrochlear branches of the ophthalmic nerve supply sensation to the skin of the radix, the rhinion, and the cephalic portion of the nasal sidewalls (11). The external nasal branch of the anterior ethmoidal nerve supplies the skin over the dorsum of the caudal nose down to and including the nasal tip. This branch emerges between the caudal edge of the nasal bone and the upper lateral cartilage (ULC) and courses in the SMAS layer. Injury to this nerve during intercartilaginous or cartilage-splitting incisions can result in tip numbness (11). Branches of the infraorbital nerve provide sensation to the side of the lower half of the nose and the lateral vestibule. The nasopalatine nerve, a branch of V2 that enters the nose through the incisive foramen, provides the major sensory supply to the posterior two-thirds of the nasal septal mucosa, maxillary gingiva, and anterior palatal mucosa. This nerve may be injured during surgery involving the maxillary crest or nasal floor and can result in temporary numbness near the incisors (12).

Inner Lining

The nasal vestibule is lined with keratinizing squamous epithelium. The surfaces of the nasal cavities, with the exception of the superior olfactory epithelium, are covered by ciliated stratified or pseudostratified respiratory epithelium (13). Because of its high vascularity, the vestibular epithelium and intranasal mucosa are excellent sources of local flaps for reconstruction of the inning lining in full-thickness nasal defects. In such procedures, a free cartilage graft is often used to rebuild structure for the nose. The rich vascular intranasal lining flap nourishes the cartilage graft from its undersurface. Common inner lining donor sites are the nasal septum or nasal vestibule. These flaps are discussed in more detail in Chapter 165. During routine rhinoplasty, care must be taken to preserve vestibular skin in the internal nasal valve area to avoid web formation and nasal valve stenosis (14).

Variant Anatomy

Thickness of the SSTE varies with ethnicity, age, and gender. Noses with thin, less sebaceous skin assume a shape that closely matches the underlying cartilaginous and osseous structure. In contrast, the underlying nasal architecture does not accurately transmit through the soft tissue envelope in thicker-skinned noses. These concepts are critical in rhinoplasty.

In the thick-skinned individual, modifications of the underlying framework, particularly reductive alterations, may not result in significant changes in external appearance because of poor redraping of the overlying SSTE. In these patients, the surgeon should consider augmenting areas of relative deficiency to create a framework that pushes and stretches the thick SSTE into a desirable shape. In such cases, overall proportion of the nose becomes more important than absolute size. Because a thick SSTE cannot conform onto the underlying structure after reduction, scar tissue may fill the resulting void. An example is the soft tissue/scar pollybeak that results after aggressive supratip hump reduction in a thick-skinned individual. Little to no external lowering of the supratip convexity occurs as the cartilaginous hump is simply replaced by scar beneath a noncompliant SSTE.

In patients with thin skin, even small irregularities of the underlying structure may become evident after surgery as the soft tissue envelope redrapes very closely to the framework below. In these cases, care must be taken to camouflage grafts, edges of bone and cartilage, and any other contour irregularities. Graft must be placed in a precise manner, and any edges that may transmit through the skin should be beveled or crushed to blend seamlessly into surrounding structures. Soft tissue or crushed cartilage onlay grafts may aid in camouflaging irregularities.

SKELETAL FRAMEWORK

The skeletal framework of the nose may be divided into thirds: the upper third consisting of the osseous vault; the middle third consisting of the upper cartilaginous vault; and the lower third consisting of the lower cartilaginous vault. The nasal septum, consisting of a bony and a cartilaginous portion, provides support in all three sections

and divides the nasal cavity into two lateral halves. In this section, these structures are discussed individually, with an emphasis on anatomic forms and their variations. In a later section, the interrelations of these bodies as they pertain to nasal structural mechanics are discussed.

Septum

The nasal septum is a sagittal midline structure that divides the nose into two cavities and provides structural support to the osseous and cartilaginous vaults (15). The septum is divided into a cephalic–posterior osseous septum, composed of the perpendicular plate of the ethmoid and the vomer, and a caudal–anterior cartilaginous septum, consisting of the quadrangular cartilage.

The perpendicular plate of the ethmoid forms the dorsal aspect of the osseous septum. Its superior attachment consists of the frontal bone and its nasal spine anteriorly and the cribriform plate posteriorly. Anterosuperiorly, it articulates with the inward projection of the nasal bones in the midline. Anteroinferiorly, it borders the quadrangular cartilage, and posteroinferiorly, it borders the vomer. The thickness of the perpendicular plate of the ethmoid varies considerably, and it is rarely pneumatized. Because it is attached to the cribriform plate, aggressive lateral force high on the osseous septum may lead to fracture of the skull base and resultant cerebrospinal fluid leak or olfactory bulb injury.

The vomer, one of the bones that make up the skull, is shaped like the keel of a boat. In a midsagittal view of the skull, its superior edge forms a line connecting the sphenoid sinus to the anterior nasal spine. Superiorly, the vomer articulates with the perpendicular plate of the ethmoid. Inferiorly, it attaches to the midline nasal crest of the palatine bone posteriorly and the maxilla anteriorly. Anterior to its articulation with the vomer, the maxillary crest forms a groove into which the quadrangular cartilage sits. The posterior free edge of the vomer forms the posterior border of the choanae.

The quadrangular cartilage comprises the cartilaginous septum. This structure rests within a groove in the nasal spine and maxillary crest inferior to it. This ventral surface is typically thickened in comparison to the remainder of the structure. Dorsally, the quadrangular cartilage forms the contour of the nasal bridge externally. The ULCs articulate with the cephalic aspect of the quadrangular cartilage, forming the dorsum of the central third of the nose. The most caudal portion of the cartilage extends anterior to the nasal spine and is the least rigid portion (Fig. 179.9). Three angles may be identified at the caudal edge of the septum (Fig. 179.10). The anterior septal angle is usually the most anterior projection of the septum and forms the transition between the dorsal and caudal components of the supportive cartilaginous septal L-strut. The domal regions of the LLCs are in intimate proximity and typically project beyond the anterior septal angle, creating the external

(From Tardy ME. *Surgical anatomy of the nose.* New York: Raven Press, 1990, with permission.)

topography of the nasal tip. Because of this relation, deviations of the anterior septal angle may cause distortions of nasal tip position. The posterior septal angle is located at the quadrangular cartilage articulation with the anterior nasal spine. The intermediate septal angle lies between the anterior and posterior septal angles.

The membranous septum is the soft tissue continuation of the cartilaginous septum. Consisting of a central layer of subcutaneous areolar tissue between vestibular skin on each side, the membranous septum bridges the caudal edge of the cartilaginous septum to the medial crura and columella. Contained within it are the ligamentous attachments of the medial crura to the caudal septum. Because of a lack of cartilage, it is mobile and displaces easily with manipulation of the columella.

The septum is lined with an inner layer of perichondrium or periosteum covered by an outer layer of mucosa.

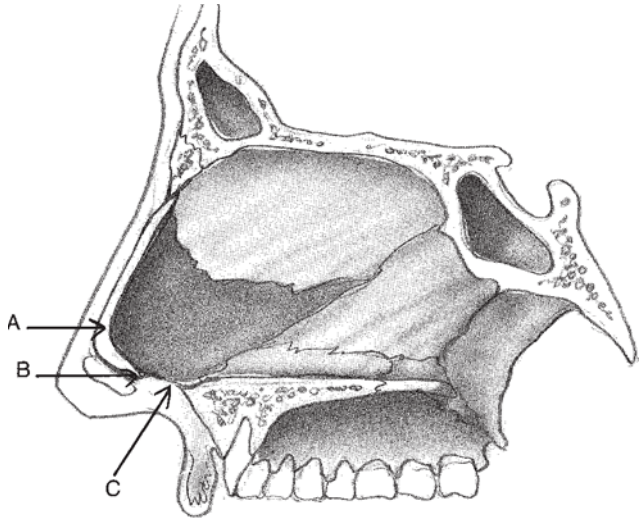

Figure 179.10 *Arrows*, The three anatomic angles composing the caudal aspect of the nasal quadrangular cartilage. *A*, Anterior septal angle; *B*, midseptal angle; *C*, posterior septal angle.

The two layers of septal lining are closely attached and together contain the vascular and nervous supply to the septum. Separation of the mucoperichondrium from the underlying cartilage, as may occur in traumatic or postsurgical septal hematoma, may lead to ischemic necrosis of the affected septum and result in a perforation or a saddle-nose deformity. When portions of septal cartilage or bone are removed during surgery, the lining flaps from each side of the septum are left to readhere and scar. Thus, during septal surgery, perforations may also result after opposing bilateral mucosal tears are created. Because the perichondrial and periosteal layers bear the majority of the biomechanical strength of the septal lining, the surgeon must remain deep to these layers during flap dissection, to maximize strength of the resulting lining flaps and reduce the risk of perforation. If the flap elevation occurs in a submucosal plane, the perichondrium or periosteum may be inadvertently resected with the septal cartilage and bone, leaving only the relatively weak mucosa and increasing the risk of perforation (16).

Variant Anatomy

Differences in the size and development of the nasal septum account for many of the functional and aesthetic variations in the nose. Because the septum is attached to the cartilages that determine nasal shape (LLCs and ULCs), its overgrowth may lead to excessive projection of these structures. In these situations, the septum pulls the cartilaginous elements of the nose under tension—the underpinnings of the so-called tension-nose deformity. Such noses are characterized by a high cartilaginous dorsum, a tip-defining point that is determined by a projecting anterior septal angle (instead of the domal angle of the LLC), and a low-hanging columella that is created by a prominent caudal septal border. In such patients, conservative trimming of the septum may be necessary to create a less conspicuous profile.

An inverse relation exists between the sizes of the cartilaginous septum and osseous septum. Patients with short nasal bones and long ULCs tend to have a greater abundance of quadrangular cartilage and less vomer and ethmoid plate. The opposite is true in noses with long nasal bones and short ULCs. This relation may help the rhinoplasty surgeon predict how much septal cartilage will be available for graft harvesting before surgery.

The septum rarely exists in a true midsagittal plane. Deviations from the midline have both functional and cosmetic implications. Particularly along the floor of the nasal airway, deviations may cause considerable airway obstruction. Most often, a combination of cartilaginous and osseous deformities contributes to the obstruction. Surgical treatment may require removing or repositioning these deviated skeletal elements. After trauma in particular, portions of the septum may be jagged and angulated. Meticulous elevation of the septal lining from these structures is required before their removal to prevent septal perforation. Uncorrected deviations of the perpendicular plate of the ethmoid and vomer may result in persistent posterior airway obstruction after septal surgery.

Deviations of the caudal and dorsal edge of the septum have cosmetic implications in addition to functional effects. From the rhinion to the anterior nasal spine, septal deviations may translate to visible external deformities. Deviation of the mid-dorsal septum, anterior septal angle, mid-caudal septum, and posterior septal angle may lead to a crooked-nose deformity at the upper cartilaginous vault, the nasal tip, the columella, or the columellar base, respectively. These irregularities may originate from a traumatic event. However, the septum will eventually develop an inherent memory to its new shape and position. Thus, the correction of a severely crooked nose may require repositioning or replacing these septal elements (17).

Osseous Vault

The osseous vault is a pyramidal structure that, together with the bony septum, provides the principal structural support for the nose. It consists of the frontal process of the maxilla and the paired nasal bones. The cephalic portion of the osseous vault articulates with the frontal bone at the nasofrontal suture line. The superior portion of the nasal bones rests on the nasal spine of the frontal bone and also derives midline support from the perpendicular plate of the ethmoid. Caudally, the free edge of the osseous vault forms the superior portion of the pyriform aperture. The caudal edge is joined by a connective tissue to the upper cartilaginous vault in the keystone area.

Each nasal bone may be thought of as an elongated quadrangle, with its lateral long edge articulating with the frontal process of the maxilla and its medial long edge articulating in the midline with its contralateral partner. The cephalic edge at the nasofrontal suture line is narrow, whereas the free caudal edge is wider. The nasal bones are thick cephalically at the nasofrontal suture line and thin progressively toward the free caudal edge. Most traumatic nasal fractures occur in the caudal, more projecting portion of the nasal bones where they are the thinnest.

The bony pyramid of the osseous vault may be mobilized with osteotomies during rhinoplasty. Medial osteotomies disconnect the two halves of the osseous vault so each may be moved independently, and lateral osteotomies free the anterior sidewall of the osseous vault from its attachment to the rest of the frontal process of the maxilla. The lateral osteotomy is made on the frontal process of the maxilla and preserves the nasomaxillary suture line. A wide range of height, length, and width of the osseous vault occurs, and this should be taken into account in the planning of osteotomies.

Variant Anatomy

The overall thickness of the nasal bones varies by age, gender, and ethnicity. As elsewhere in the body, the nasal

bones are subject to age-related osteopenia and may become thinner and more fragile over time, particularly in women. Such individuals are particularly prone to nasal fractures, even with moderate-energy trauma. After such injuries, it may take these patients longer to reach stable osseous union, potentially prolonging the time window in which closed nasal reduction may be performed. Surgical osteotomies should be performed cautiously in noses with thin, fragile bone, as a higher risk exists of creating overly mobile, free-floating osseous segments. In contrast, patients with thick, rigid nasal bones may be relatively resistant to nasal fractures, may heal rapidly after fractures occur, and may require greater force to create adequate osteotomies during surgery. Often in rhinoplasty, the goal is to create a modest narrowing of the osseous vault. This may be accomplished through a controlled back-fracture of the bridge of bone that remains between the cephalic termination of the medial and lateral osteotomies. In patients with thick bone, this osseous bridge may resist back-fracture. In such cases, the area of intact bone may be weakened before back-fracture through a transcutaneous bridging osteotomy. By using a 2-mm osteotome, a series of small perforations may be made through the bone through a single entry point in the skin.

Variations in the width and medial–lateral position of the nasal bones may be hereditary or acquired. Hereditary variations are more likely to manifest as a symmetrical but unusually narrow or wide osseous vault. Gross asymmetries are more likely to be acquired traumatic injuries. In many cases, these are injuries incurred very early in life or even during the birth process. Correction of these deformities typically requires repositioning of the nasal bones through surgical osteotomies. The lateral osteotomies should lie lateral to the bony deformity so that it may be incorporated into the segment of mobilized bone. In cases in which the nasal bone has a very convex, concave, or irregular topography, the bone may need to be mobilized in more than one segment to correct the contour irregularities. In such situations, an intermediate osteotomy may be necessary between the medial and lateral osteotomies. When several osteotomies are needed, they are performed medial to lateral so that the cuts are always made on stable bone. The distance of osteotomies needed to mobilize the nasal bones is dictated by their length, which is also highly variable.

Upper Cartilaginous Vault

The upper cartilaginous vault consists of the paired, shield-like ULCs that are fused in the midline to the dorsal edge of the cartilaginous septum. The septum and the ULCs are fused early in embryonic development and form a single structural unit in this area (18). Although the cartilaginous septum provides support to the ULCs at their midline dorsal fusion, the nasal bones provide the majority of reinforcement to the ULCs at their cephalic margin, the keystone area. Here, the ULCs overlap the caudal border of the osseous vault, extending cephalad under the bony arch for a distance of up to 11 mm. This attachment is critical in maintaining the structural integrity of the nasal framework. Vigorous downward force on the ULCs can lead to their dislocation from the nasal bones, a deformity that causes collapse of the upper cartilaginous vault. Because the nasal bones stabilize the ULCs at their cephalic aspect, the upper cartilaginous vault is less rigid and more mobile caudally.

The upper cartilaginous vault is wider cephalically where the ULCs take on a more horizontal course as they articulate with the septum. The arch of the ULCs closely follows the arch of the nasal bones in this region. Caudally, the ULCs slope more acutely away from the dorsal septum, creating a narrower dorsal line. At their caudalmost aspect, a free edge of the ULCs may diverge away laterally from the septum. This relatively narrow area of the upper cartilaginous vault corresponds intranasally to the internal nasal valve area, the region with the greatest nasal airway resistance. These regional variations are easily visualized on cross sections (Fig. 179.11).

Along with the cartilaginous septum, the ULCs determine the appearance of the middle third of the nose. The transition between these structures should be smooth and unbroken. Surgical alterations in this area, such as with hump reduction or spreader grafting, should result in a smooth, coplanar dorsal surface.

Variant Anatomy

The distance from nasion to rhinion defines the cephalic–caudal length of the osseous vault. The upper cartilaginous vault refers to the area of the nose from rhinion to the caudal edge of the ULCs. Despite their common nomenclature of upper and middle thirds of the nose, the lengths of these regions rarely occupy exactly one-third of total nasal length. The lengths of the osseous vault and upper cartilaginous vault have an inverse relation. That is, individuals with long nasal bones have a short upper cartilaginous vault and vice versa. The length of the upper cartilaginous vault typically corresponds to the length of the quadrangular septal cartilage. Thus, the presence of long nasal bones and a short upper cartilaginous vault should alert the surgeon that a relative deficiency of septal cartilage may be present.

The relative lengths of these areas have significant implications on the supportive mechanism of the internal nasal valve. Patients with long nasal bones and short ULCs tend to have more support of the internal valve area because of a greater contribution of the rigid support provided by the nasal bones. In contrast, long ULCs have less rigid osseous support and are therefore more prone to collapse, particularly at their caudal aspect in the area of the internal nasal valve (Fig. 179.12). Individuals with preexisting narrowing in this region may already have nasal

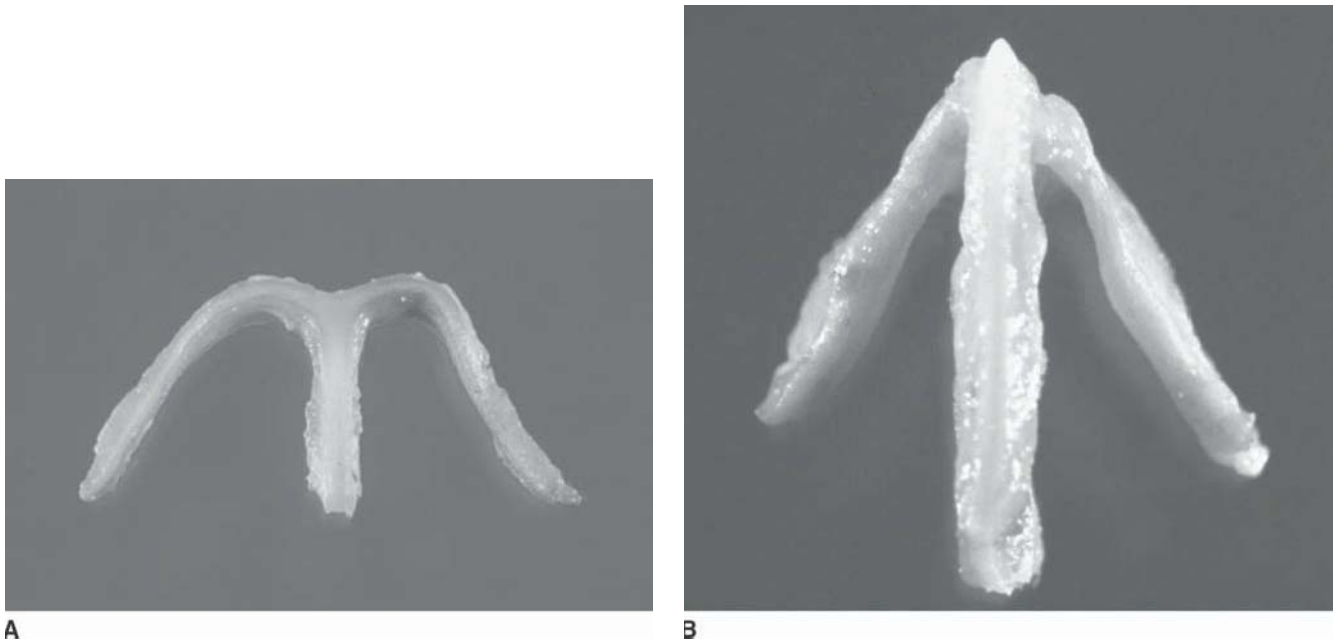

Figure 179.11 **A**: Cross section of the upper cartilaginous vault just below the rhinion. The broad arch of the ULCs closely follows the caudal margin of the nasal bones in this region. **B**: Further caudal in the area of the internal nasal valve, the structures are more flexible and a much narrower relation exists between the ULCs and nasal septum. valve insufficiency or collapse of the ULC during inspiration. These patients are predisposed to develop postrhinoplasty nasal obstruction after dorsal hump reduction. In such cases, the articulation of the ULCs and septum is resected with the hump, leaving the ULCs unsupported along the dorsum. Ensuing inferomedial collapse of the ULCs occurs, leading to internal valve narrowing, medial pinching of the central area of the dorsal line, and the inverted-V deformity, in which cephalic ULC collapse reveals the outline of the V-shaped caudal border of the nasal bones. To prevent such complications, the ULC should be resupported onto the septum with a technique such as spreader grafting.

Lower Cartilaginous Vault

The key elements in the lower cartilaginous vault are the paired lower lateral (or alar) cartilages. Perhaps more than

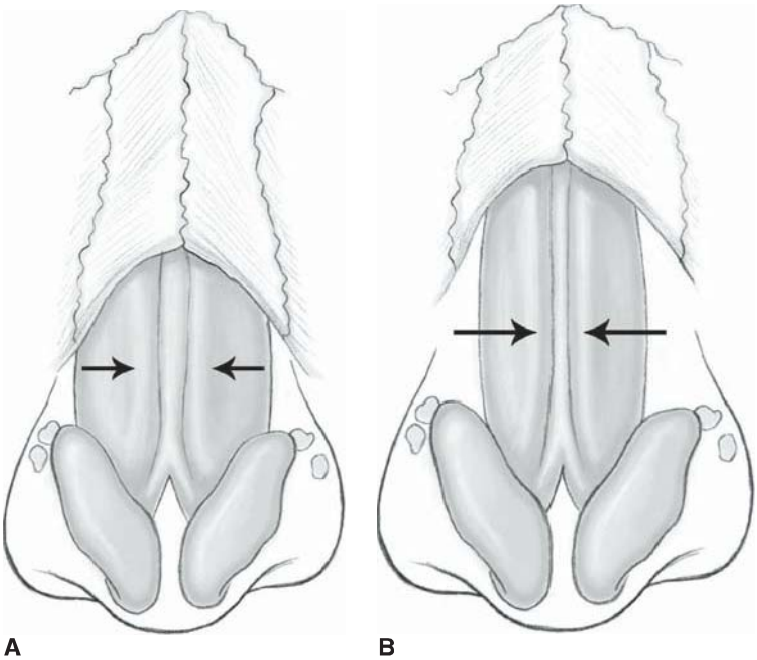

Figure 179.12 **A**: Long nasal bones create more stabilization of the caudal cartilaginous elements of the nose with less tendency for inferomedial collapse of the ULCs with inspiration or with scarring after hump reduction. **B**: Short nasal bones and a long upper cartilaginous vault may cause narrowing of the ULCs after they are separated from the nasal septum following hump reduction. Restabilization with spreader grafts may prevent this complication in such patients.

anywhere else in the nose, endless anatomic variations and divergences are found between individuals in these structures. However, the extent to which the LLCs determine the shape and configuration of the nasal tip and base is variable, depending on the thickness of the SSTE and the tensile and compressive forces imparted to these areas by the attachments to the surrounding fixed structures of the nasal septum, pyriform aperture, ULCs, and nasal bones. Nonetheless, surgical modifications of the nasal tip and base in rhinoplasty almost always involve some modification to the shape or position of the LLCs.

With the septum, the LLCs provide support to the nasal tip. Each LLC may be considered in three sections: the medial crus, the intermediate crus, and the lateral crus. The three areas are not necessarily distinct anatomic entities but transition from one to the next through a series of bends and undulations in the continuous roll of cartilage. These myriad turns and divergences create the nuances of this structure, which then form the unique external topography of each nasal tip. Two distinct angles, however, are fairly consistent in most noses and consequently are generally conceptualized as transition points that separate the three crura: the lateral genu and the medial genu (Fig. 179.4A). The subsequent discussion covers the general anatomy of each subsite of the lower lateral crura. The more commonly encountered variant anatomy is then discussed. The role of the LLCs as they pertain to mechanical stabilization of the nose is discussed subsequently.

The Medial Crus

With their connection to the caudal septum, the medial crura form the structural support of the columella. The width of the LLCs is narrowest in this region and may be as little as 4 to 5 mm. Each medial crus may be divided into an anterior columellar segment and a posterior footplate segment. On base view, each columellar segment parallels its contralateral counterpart and is connected to it and the caudal septum by fibrous tissue. The footplate segment flares posterolaterally and contributes to the normal widening of the columella at its base or pedestal. On the lateral or base view of an ideal Caucasian nose, the anterior limit of the medial crus corresponds to the columellar–lobular junction at the apex of the nostril (Fig. 179.4).

Variant Anatomy

Variation in the length and shape of the medial crus affects the appearance of the nasal base and position of the nasal tip (19). A short medial crus results in a short columella and a small anteroposterior dimension of the nostril. This tends to result in deficient nasal-tip projection and a small nostril–lobular ratio. A long medial crus that extends anteriorly beyond the apex of the nostril creates a flat, projecting nasal tip. Endless variations exist in the degree of symmetry, curvature, flare, and smoothness of these structures. The intervening soft tissue between the columellar segments may camouflage irregularities, but a thin SSTE may lead to a bifid appearance of the columella. In general, the goals during surgery are to place the medial crura into a symmetrical, midline position. Fixation sutures to resecure the medial crura are a reliable technique to this end, but care must be taken to maintain a normal relation between the crura and surrounding structures. For instance, the medial crura should be bound together only at their cephalic borders to retain the natural flare of the caudal edges so as to maintain adequate columellar width (11). Even a small degree of malposition of the medial crura may have significant impact on nasal tip rotation, projection, columellar show, and nasolabial angle. Fixation, therefore, must be executed with enormous forethought and meticulous technique.

The width of the individual medial crura and their distance from each other determine the width of the columella. In some cases, the normal flare of the posterior medial crura (footplates) is exaggerated, leading to a wide columellar base, which may compromise airflow at the nostril aperture. Caudally positioned medial crura may result from excessive cartilaginous width, lax ligamentous attachments to the caudal septum (wide membranous septum), or caudal overgrowth of the septum, which tensions the medial crura downward. Particularly in the presence of retracted nasal ala, low medial crura will lead to excessive columellar show. Such patients may complain that their nostrils are too conspicuous. Surgical correction usually involves elevating or trimming the caudal margin of the medial crura.

The Intermediate Crus

Also called the domal segments, the intermediate crura bridge the medial and lateral crura, extending from the medial genu to the lateral genu. This structure represents the transition from the convergent and divergent portions of the paired LLCs. The region of the lateral genu is often the anteriormost projecting point of the LLC and may correspond topographically to the tip-defining point. In this region, the intermediate crus may narrow abruptly, rendering it susceptible to transection during surgery. The angle formed between the two intermediate crura as they flare away from each other laterally is termed the angle of divergence (Fig. 179.13). The ideal angle is approximately 60 degrees and provides a natural-appearing width to the infratip lobule as it transitions from the columella to the nasal tip on frontal or basal views. The intermediate crura also diverge from the medial crura in a cephalic direction by approximately 50 degrees. Externally on lateral view, this bend corresponds to the columellar–lobular angle, dividing the nasal base into the infratip lobule anteriorly and columella posteriorly—the basis of the double break.

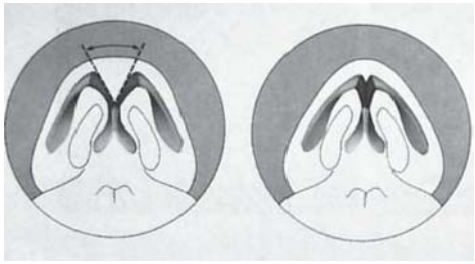

Figure 179.13 The intermediate crura bridge the lateral and medial crura of the LLCs. The angle of divergence is shown on the left. If the intermediate crura are widely bifurcated, a broad trapezoid appearance of the tip results, as shown on the left. If the intermediate crura are closely opposed, a triangular appearance results, as shown on the right.

Variant Anatomy

Variations in the length and curvature of the intermediate crura and the degree of angulation at the medial and lateral genua determine the shape of the infratip lobule on frontal and basal views. Gentle turns at the genua and a smooth convex curvature of the intermediate crus produce a convex domal segment. A broad and flat intermediate crura with angulated connections at the genua result in a "boxy" configuration. If the intermediate crura are concave, a "double-dome" segment is created (2). Variation in the angle of divergence also will affect the shape of the tip lobule. A narrow angle of divergence results in a narrow lobule and creates a more triangular appearance to the tip on base view. An angle of divergence approaching 90 degrees produces a boxy tip that appears trapezoidal on base view. These variations in the cartilage configuration may not be reflected in the shape of the tip lobule if overlying skin is thick (Fig. 179.13).

Excessive thickness or convexity of the intermediate crura in the cephalic–caudal dimension may manifest externally as bulging of the infratip lobule. On lateral view, the tip may appear rounded, transitioning to the infratip lobule with one unbroken curve, rather than as a distinct normal double break.

The Lateral Crus

The lateral crus extends from the lateral genu of the LLC posteriorly. Normally, it assumes a gentle convex shape and parallels the alar rim for its medial half, then flattens and turns posterosuperiorly for its lateral portion, ending short of the pyriform aperture. It generally becomes wider as it leaves the lateral genu and then narrows again toward its lateral termination. It is typically the broadest portion of the LLC. Although a centimeter in width is a reasonable estimate of average width, tremendous variation exists (20).

A portion of the medial cephalic borders of the lateral crura may overlap. In this region, the LLCs may be connected to each other and to the caudal border of the ULC by fibrous tissue. The connection to the ULCs is often reinforced by overlapping segments of cartilage. This scroll area is highly variable and may be thickened in comparison to other parts of the LLC (Fig. 179.14).

Variant Anatomy

The variations of lateral crus anatomy are too numerous to detail (20), but some of the more commonly seen variations are discussed herein. Variations in the width and curvature of the lateral crura greatly influence the appearance of the tip and ala. The widest portion of the lateral crus may vary from 7 to 15 mm (20). Broad convex lateral crura impart a bulbous, amorphous appearance to the tip. The concept is similar to the relation of dorsal height and the appearance of width discussed earlier. In a normal nose, the relative narrowness at the nasal tip/domes and the

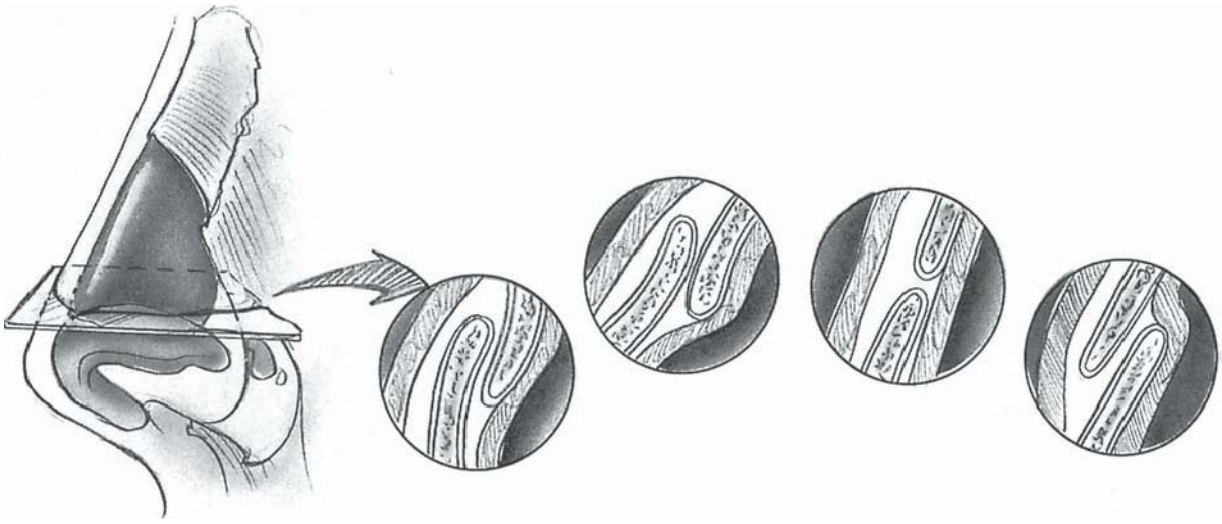

Figure 179.14 A variety of anatomic relations between the cephalic margin of the LLC and the caudal margin of the ULC is found in dissection of cadaver specimens. As individuals age, the intimate relation between the cartilages may be lost. (From Tardy ME. *Surgical anatomy of the nose.* New York: Raven Press, 1990, with permission.)

relative width at the alar base create a visual contrast that makes the tip look appropriately distinct and refined. If the transition from the tip to base is characterized by widely curving lateral crura and nasal ala, this contrast is indistinct, creating the appearance of a wide nose. Correction of such a deformity may require techniques to straighten the overly curved lateral crura, such as suture modification or structural grafting. Aggressive techniques that focus only on narrowing the domes themselves and ignore the convexity of the lateral crura may result in no improvement of the appearance of the tip while incurring structural and cosmetic complications.

Less commonly, the LLCs may be concave as they diverge away from the domes. Externally, this may manifest as a hollow, sunken appearance at the alar lobule with an exaggerated supra-alar crease. If severe, the concavity may narrow the nasal vestibule, impairing nasal airflow. Surgical correction may require structural onlay or underlay grafting, resection and graft replacement of the concave segment, or simply flipping over the concave segment through excision, inversion, and suture fixation.

The strength and thickness of the intermediate and lateral crura determine much of the inherent support of the nasal tip. Stronger cartilage is more resistant to alteration and may result in visible or palpable deformities after surgery. The surgeon must remember Tardy's admonition of the risks of bossae formation after excisional techniques to narrow the tip in patients who possess the triad of tip bifidity, thin skin, and strong LLCs. In such situations, the thick edges of cartilage gradually become apparent through the thin skin envelope as contracture distorts the disrupted tip structures. Modification through suture techniques with avoidance of LLC division is less likely to lead to bossae formation in such patients.

As discussed, the medial aspect of the cephalic border of the lateral crura may overlap for a variable distance. This degree of overlap depends on the overall cephalocaudal position of the lateral crura. In extreme cases, the trajectory of the upper border of the lateral crura is actually straight cephalad, each edge overlapping with the other in the midline over the dorsal septum. In such noses, the lateral crura may diverge from the midline only near its lateral termination. External deformities may be discernable in such patients, particularly in those with thin skin. The classic description is the parenthesis deformity, so named because the bulky outline on frontal view created by the cephalically positioned lateral crura looks as if it is framed by two parentheses on either side of the supratip—"( )." A high dorsum at the supratip on the lateral view in such patients may be misdiagnosed as overdevelopment of the quadrangular cartilage in this region when it may be caused by the overriding cephalic lateral crura. Lowering the dorsum in such patients may require trimming of the cephalic margin of the lateral crura or suture repositioning of the lateral crura instead of dorsal septal excision, the conventional approach to profile reduction. Another consequence of cephalic lateral crura is the resultant decrease in support to the alar margin. With the lateral crus angled further cephalad, less structural reinforcement is provided to the caudal alar rim, predisposing patients to alar pinching or external nasal valve insufficiency.

Another variation of the lateral crus that may affect nasal airflow is inward (medial) recurvature of its lateral terminus. In some patients, this creates a visible or palpable mass in the lateral nasal vestibule, potentially impairing nasal airflow. In other cases, the deformity may not be apparent until after other rhinoplasty maneuvers have caused medialization of the lateral nasal wall, such as dome-narrowing or tip-projecting maneuvers. Correction may involve simple excision of this portion of the lateral crura if it is caused by overly long, redundant cartilage. Repositioning the area with a stiff underlay graft may be needed in other situations.

Asymmetries of the lateral crura may create tip irregularities and contour deformities. When these asymmetries are severe, they may create tip deviation, even in the presence of a midline caudal septum.

NASAL BASE

The main structures of the nasal base are the paired nasal alae, the nasal sills, the soft triangles, and the columella. These structures form a continuous ring around each of the nares or nostrils, the external openings of the nasal cavities. The normal Caucasian nostril should be oval, with a vertical axis less than 45 degrees from the columella and a nostril-to-infratip lobule ratio of 2:1. Ethnic differences account for significant divergences from these values.

The *nasal ala* is the most lateral wing-like portion of the nostril (21). The main body of the alar lobule is devoid of cartilaginous structure and consists of fibroareolar tissue. Because of this, the shape of the alar lobule is not typically sculpted directly in rhinoplasty. However, cartilaginous elements frame the nasal ala, and their modification alters its shape. The lateral crus of the LLC sweeps over the superomedial portion of the ala. The sesamoid cartilages are located in the soft tissue overlying the pyriform aperture above the ala. Their number is variable, with 0 to 5 cartilaginous bodies present. Interlaced with collagen and fibrous tissue, these accessory cartilages form the sesamoid complex, the connection between the mobile termination of the lateral crus to the rigid pyriform aperture rim.

The insertion of the nasal ala to the face at the junction of the lip and cheek subunits determines the width of the nasal base. Interalar width refers to the horizontal distance from one alar crease to the other. The overall width of the nostrils is also affected by the alar flare, as defined by the degree of bowing of the ala above its insertion. The insertion to the face is three-dimensional, paralleling the curved alar crease that frames the nostrils laterally. Along with the position of the columella, the vertical position of the alar insertion determines the degree of columellar show.

The *nasal sill* is the soft tissue continuation of the ala as it curves medially to join the columella at the nasal spine. It represents the floor of the nostril and is generally wider in those individuals with a large interalar width. Inadvertent injury to the thin skin in this area may lead to visible scar or contraction leading to stenosis of the nostril.

The *soft triangle* is a small base-up triangular subunit bordering the columella medially, the ala laterally, and apex of the nostril anteriorly. This area is unique in that it contains minimal subcutaneous tissue. The external nasal skin folds directly onto the internal vestibular skin, spanning across the genua of the LLC. Because of the lack of subdermal support, this delicate skin is prone to scar contracture if violated. Cicatrix in this area can also lead to reduction in the cross-sectional area of the nostril.

The *columella* is made up of the paired medial crura, which are bound together with fibrous attachments and covered with a skin envelope continuous with the membranous septum. In most individuals, the columella is fairly mobile, limited only by the attachments of the medial crura to the relatively fixed caudal border of the cartilaginous septum. The shape of the columella is determined by the paired medial crura and the most caudal edge of the cartilaginous septum. Distortions of the columella on base view often result from a deviated caudal tip of the septum, which may be easily revealed with side-to-side manipulation.

Variant Anatomy

The alar base represents one of the most highly variable regions of the nose. Width of the alar insertion is rarely within the confines of the medial canthi, as widely described, even in the leptorrhine Caucasian nose. Overall nasal alar width results from the combination of interalar width and alar flare. Patients of Asian and African descent are more likely to have greater alar base width, alar flare, a shorter columella, and more horizontally oriented nostrils. These external differences are ascribable to underlying variations of structural anatomy: weaker, flatter LLCs; thick SSTE; and deficiency of the premaxilla and nasal spine (22). Thickness of the alar wall is also inconstant and reflects the amount of subcutaneous fatty fibroareolar tissue. These variations account for a wide range of nostril orientations and resultant deviation from the "normal" nostril-to-infratip lobule ratio of 2:1. Farkas et al. (23) categorize the variants of nostril position into seven types ranging from vertical to horizontal.

It is crucial that the rhinoplasty surgeon precisely diagnose the cause of a wide alar base before surgery. Some individuals have a wide interalar distance associated with wide nasal sills as the predominant cause. Correction of such a deformity might require segmental excision and closure of a portion of the nasal sills or suture technique to narrow the sills. Other patients may have a normal alar insertion with normal interalar distance but excessive alar flare. Reduction of the ala above the insertion would then be indicated. Reduction of the sill without addressing the alar sidewalls in such patients may actually lead to an exaggeration of the flare, as the ala are forced to curve more acutely. Many patients have components of both an increased interalar width and alar flare, requiring treatment of both the sill area as well as the alar sidewalls.

In addition, the internal and external circumferences of the nostrils must be considered so that the geometry of the excision may be appropriately adjusted. Some individuals have a normal or even small inner nostril circumference but have an overall wide alar base because of thick alar walls. Such individuals benefit from a triangular or trapezoidal wedge excision such that more tissue is excised from the external rim of the nostril than is removed from the inner circumference. In extreme cases, the alar sidewall itself may be debulked and thinned through an alar rim incision.

MECHANICS AND STABILITY

Structural Elements and Relations

Considerations regarding the mechanical stability of the nose are too often overlooked in rhinoplasty. Compromise to the structures and relations that maintain the nose's architecture leads to long-term complications impairing both function and cosmesis. In this section, the regional anatomy of the nose is revisited as it pertains to the mechanical stabilization of the nose. Also discussed are several conceptual models, some of them co-opted from engineering principles, which are commonly invoked to help surgeons conceptualize the elements of nasal structural stability.

The stability of the nose derives from the strength and resiliency of its complex anatomic elements and their various interconnections. Three echelons of support may be conceptualized, each contributing various degrees of stabilization. First, the osseous framework, including the nasal bones, pyriform aperture, osseous septum, and nasal floor, provides the rigid foundation onto which the cartilaginous and soft tissue elements are built. Second, the rigid quadrangular cartilage, which is fixated to bone along its ventral and cephalic borders, directly supports the upper and lower cartilaginous vaults. And third, the intrinsic architectures of the LLCs, ULCs, and associated soft tissue, which are all supported by the osseous and septal foundations, provide much of the stability of the nasal tip and base. The extent to which these regions exert support to the nose depends on the region of the nose. Cephalad, the nasal bones and osseous septum provide nearly all of the rigid support. The middle third of the nose is supported by the nasal bones cephalically and by the quadrangular cartilage, which serves as a pillar beneath. The nasal tip and base area, farthest removed from the osseous framework, is the most flexible and dynamic region and depends most on the support of the cartilaginous buttressing of the caudal septum and the inherent strength of the LLCs.

Cantilever Concept

Sheen and Sheen (19) have described the nasal skeleton as a cantilever, in which the osseous vault is a stable extension of the skull. Like a cantilever, the upper cartilaginous vault projects as a beam, supported cephalically through the thick fibrous attachment of the keystone area, and carries the load of the dependent aspects of the nose along its length and at its distal end. The strength of this support depends on the length and thickness of the nasal bones. Longer bones impart more caudal support. The fusion of the osseous vault and the upper cartilaginous vault with the dorsal edge of the septum forms this structural I-beam that extends from the nasion toward the nasal tip. This complex forms the basis of dorsal support for the nose. Disruption of the connections between the nasal bones or of the ULCs or both to the septum greatly weakens the central support provided by the I-beam. This occurs during hump reduction in which the medial septal support element for the ULCs is resected. The ULCs then must rely only on the cephalic attachments to the nasal bones for support. Unless this medial support is reestablished, for example, with spreader grafts, the ULCs may collapse inferomedially, creating pinching, internal valve compromise and the inverted V.

Role of the Nasal Septum

The nasal septum supports the cantilever from its undersurface much as a support wall holds up a roof. Particularly at its caudal aspect, the quadrangular cartilage, functioning as a pillar, carries much of the burden of nasal tip support in most noses. Because the quadrangular cartilage is inherently rigid and sits firmly in an osseous foundation from the nasal spine along the maxillary crest and up the osseous septum to the nasal bones, it provides significant stabilization to the nose. The combination of the cantilevering dorsal element and the buttressing caudal element forms the basis of the L-shaped strut—the most structurally important aspect of the quadrangular cartilage. Compromise to the dorsal component leads to a saddle-nose deformity with ventral collapse of the upper cartilaginous vault. The classic example of this is quadrangular cartilage resorption after an untreated septal hematoma. Compromise to the caudal component may lead to nasal tip ptosis, particularly in the presence of weak medial crura. Traumatic or iatrogenic injury is most often the cause. This is shown in studies in which removal of the cartilaginous septum in cadavers has been shown to result in a significant loss in nasal tip projection (24). For these reasons, it is critical to maintain structural integrity of the L-strut during surgery. Although conventional teaching emphasizes the need to maintain an uninterrupted 1.5-cm-wide dorsal–caudal strut, malposition or deformity of the strut itself may be the cause of external deformities, particularly in the crooked nose. Correction of these problems may mandate the use of techniques that modify the septum and may require repositioning, camouflaging, or reconstruction of the L-strut itself (17).

Ligamentous Attachments

The nasal bones and the quadrangular cartilage serve as the rigid support structures of the nose. The more mobile caudal elements are reinforced onto these foundations through a network of fibrous adhesions. Although termed "ligaments," these connections do not conform to the strict definition of an attachment between an osseous origin and insertion. Rather, they bind the cartilaginous structures to each other, to the nasal septum, and to the pyriform aperture. Numerous histologic and cadaver studies have been conducted in an attempt to better characterize the nature of this tissue. Although the characteristics of these attachments are variably reported, most authors believe they impart a variable degree of structural stabilization to the nose and, in particular, the nasal tip. The ligamentous systems most commonly described are discussed later: the attachments between the ULCs and lateral crura, the intercrural ligaments, the attachments between the lateral crura and pyriform aperture, and the connection between the ULCs and nasal bones at the keystone region (discussed earlier).

The area of overlap between the caudal aspect of the ULCs and the cephalic margin of the lateral crura is commonly referred to as the *scroll region*, owing to the interlocking curved cartilaginous elements. In reality, the relation between these structures is highly variable. In the most common orientation, the upper borders of the lateral crura overlap above the ULCs. It is thought that the extent of recurvature of the ULC is determined by the tension exerted onto its cephalic margin as it is driven cephalad during fetal development (25). The angle of curvature may range from slight (less than 45 degrees) to complete (180 degrees). Other orientations exist with various relations between the cartilaginous structures (Fig. 179.14). Irrespective of the particular orientation, the cartilages are bound together within the scroll region by fibrous tissue, also described as the "intercartilaginous ligament" (26). This articulation forms a hinge mechanism around which the nasal tip is suspended and can flex (27). With advancing age, the intimate relation between the ULCs and the lateral crura may be lost as these ligamentous connections relax and the nasal tip settles caudally. In such cases, a diastasis between the upper and lower cartilaginous vaults may be present instead of a normal thickened scroll area.

The intercrural ligament, also termed "the ligamentous sling" (28), binds the medial aspect of the lateral crura, the intermediate crura, and the medial crura to each other. This ligamentous structure is thought to pull the paired LLCs into the midline. It is widely believed that fibrous attachments connect this ligament to the caudal margin of the septum in the region of the medial crura, providing

additional tip support at the base of the nose. Some studies, however, dispute the existence or the importance of such connections (29–31). The contribution of the intercrural ligament in overall tip support, however, is fairly clear. After division of the intercrural ligament, nasal tip support is decreased by 25% to 35%, as measured by tensiometry (30). These studies highlight the need to restore the integrity of these attachments after they are disrupted during surgery, to prevent postoperative loss of tip support. An effective means to this end is through stabilization of the tip at the nasal base. Such techniques involve suture stabilization of the medial and intermediate crura to a stable midline foundation, such as a long nasal septum, a nasal septal caudal extension graft, or a columellar strut (1).

The connection between the lateral crura and the pyriform aperture consists of collagen fibers arranged irregularly with muscular fibers interspersed (31). This connection, which in some individuals contains embedded sesamoid cartilages, also is called the *sesamoid complex or the lateral crural complex*.

Nasal Tip Support: Tripod Concept

The nasal tip is a complex structure whose integrity is maintained by an interrelated network of supporting mechanisms made up of both the tip cartilages and the ligaments that connect them. One classic model used for understanding nasal tip support and dynamics is the tripod analogy (32). The apex of the tripod is the nasal tip, with each of the lateral crura extending cephalolaterally to form two legs of the tripod, and the conjoined medial crura together forming the third leg. Modification of the limbs of the tripod results in changes in nasal tip position. Shortening the limbs results in a loss of tip projection, whereas lengthening increases projection. Tip rotation increases as a result of either truncating the lateral limbs or extending the medial limb. The opposite maneuvers lead to decreased tip rotation. Although the tripod concept is useful to conceptualize these dynamic consequences of crural modification, the analogy falls short as a model for tip structural support. Unlike a true tripod, the LLCs do not rest on a stable surface. Rather, their "feet" are tethered by ligamentous connections to the osseous rim of the pyriform aperture and nasal spine, whereas the apex is tensioned anteriorly and cephalad by the intercrural ligament and the scroll (33). Thus, the nasal tip tripod is a dynamic unit that is suspended and supported by its rigid surrounding structures (Fig. 179.15).

Nasal Tip Support: Tardy Classification

In his classic description of nasal tip support, Tardy includes three major and six minor mechanisms (Table 179.2), each of which imparts variable degrees of support depending on individual anatomy (6). The three major mechanisms are the size, shape, thickness, and strength of the medial and lateral crura; the attachment of the medial crural footplate to the caudal border of the quadrangular cartilage; and the attachment of the caudal border of the ULCs to the cephalic border of the LLCs. The minor tip-support mechanisms are thought to augment the major ones. The classification into major and minor groups was based on clinical experience rather than on one specific structural model. Tardy advocates assessment of tip recoil through digital palpation to determine the relative importance of the various tip-support mechanisms in a given patient.

Nasal Tip Support: Other Models

Other schemas of nasal tip–support mechanisms have been reported. Based on multiple cadaver dissections, Janeke and Wright (28) proposed that the tip support is based on the fibrous connection between the ULCs and LLCs; the connection between the lateral crus to the pyriform aperture; the interdomal ligament between the paired domes of the LLCs; and the attachment of the medial crus to the caudal septum (28). Two of these are considered major tip-support mechanisms in the Tardy classification. The importance of the interdomal ligament, classified as a minor mechanism by Tardy, also is echoed by other authors who concluded that this intercrural ligament is a major tip-support mechanism and should be reconstructed during open rhinoplasty (29,34). Conversely, other authors believe that the attachment of the medial crural footplates to the septum, a major mechanism in the Tardy classification, plays only a small role in the stability of the nasal tip (33). This is supported by histologic studies of cadaveric noses showing the lack of defined attachments in this area (18,28,31). Tardy points out that minor mechanisms become major contributors (and vice versa) in certain individuals depending on their particular anatomy.

Several of the ligamentous tip-support structures have been examined in histologic detail in fresh cadaveric noses, and the results are consistent with the macroscopic findings from dissections and from clinical experience. For example, the fibrous connection between the ULCs and LLCs is shown to consist of dense collagen fibers running in the same direction and anchored firmly to each cartilage (4,7,31). This meets the histologic criteria of a true ligament.

The concept of the nasal tip as a dynamic structure is carried further in the tensegrity model of nasal tip support as proposed by Dyer (33). Applying an engineering and architectural concept to the nasal skeleton, Dyer proposed that the nasal tip may be thought of as a tensegrity structure, in which stability derives from the distribution of mechanical stress throughout all its components. Such a structure is self-stabilizing, consisting of an equilibrium of compressive and tensile elements. In the nasal tip, the LLCs and the cartilaginous septum are the compression-bearing members,

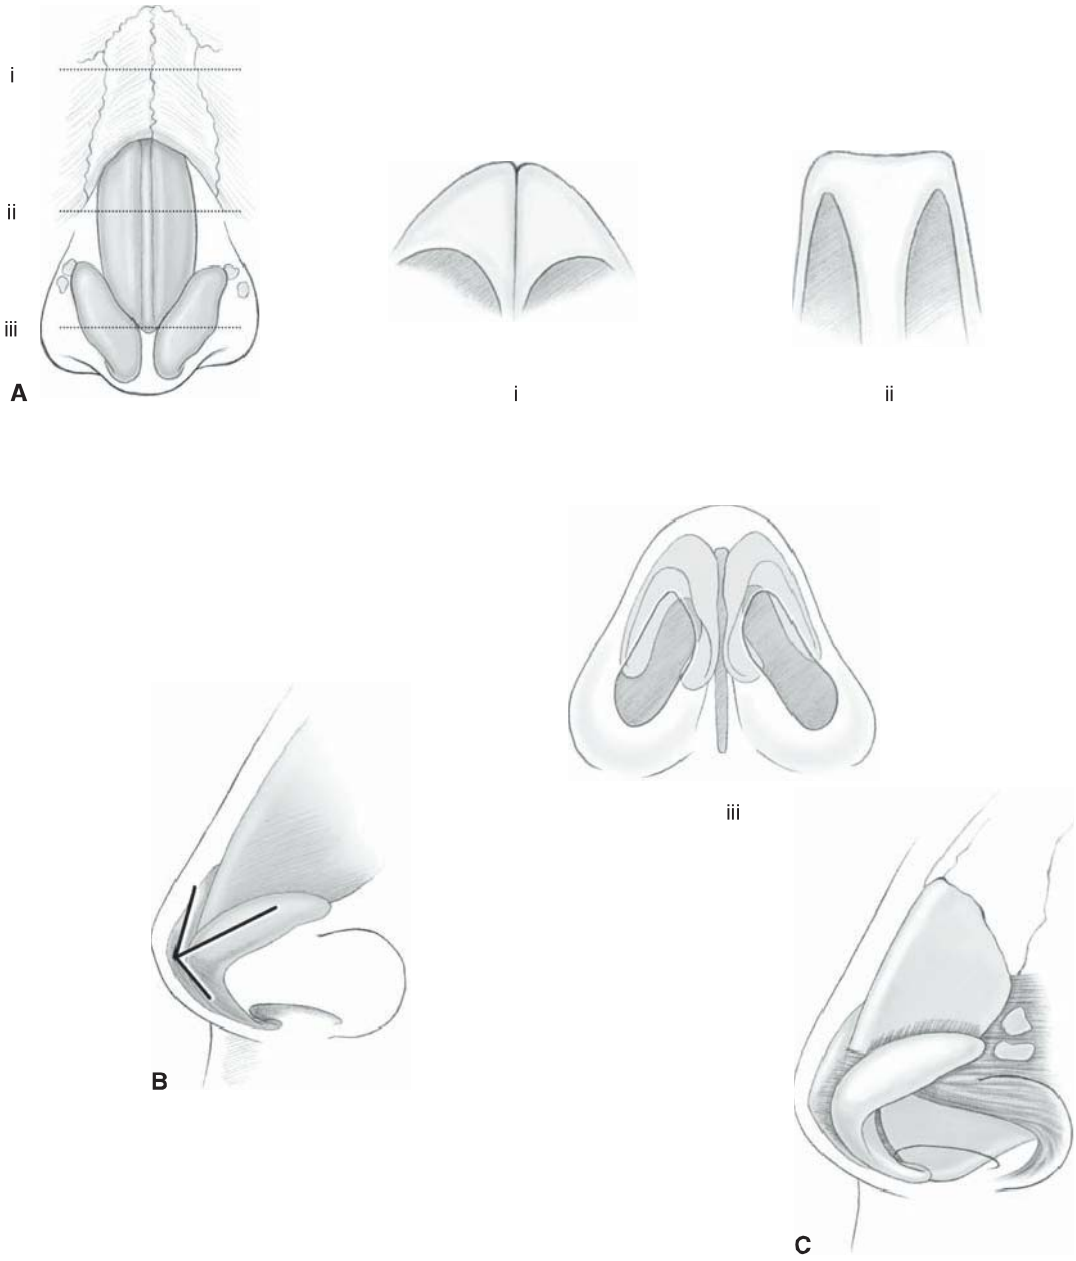

Figure 179.15 Various support mechanisms of the nose. **A**: The nasal septum functions as a supporting wall that reinforces the dorsal elements of the nose. Cross section through (*i*) osseous vault, (*ii*) upper cartilaginous vault, and (*iii*) nasal base. **B**: The two lateral crura and the conjoined medial crura create a nasal tip tripod, a model useful for understanding nasal tip dynamics. The degree to which the inherent strength of these structures contributes to nasal tip support varies significantly from individual to individual. **C**: The network of ligamentous attachments reinforce and interconnect the skeletal elements of the nose. The ULCs are connected firmly to the undersurface of the nasal bones, forming a cantilever-like support for the dorsum. The nasal tip and base are stabilized through ligamentous attachments between the lateral crura and ULC, the lateral crura and pyriform aperture, and between the two dorsal regions of each LLC.

and the fibrous, ligamentous connections are tension-bearing members. The nasal tip structure is thus viewed as an integrated structure in which disruption of one element affects the stability of the whole. Although it is difficult to test this description of nasal tip support scientifically, it is a useful concept that has already been applied to rhinoplasty techniques (33).

Areas of Structural Void

Two areas of the nose devoid of cartilaginous support are particularly susceptible to collapse in certain patients. First, the lateral nasal wall that is lateral (and often cephalad) to the termination of the lateral crura and medial to the pyriform aperture is prone to dynamic collapse with

TABLE 179.2 TIP-SUPPORT MECHANISMS

Major
- Size, shape, and resilience of the medial and lateral crura
- Medial crural footplate attachment to the caudal border of the quadrangular cartilage
- Attachment of the upper lateral cartilages (caudal border) to the alar cartilages (cephalic border)

Minor[a]
- Ligamentous sling spanning the paired domes of the alar cartilages
- Cartilaginous septal dorsum
- Sesamoid complex extending the support of the lateral crura to the pyriform aperture
- Attachment of the alar cartilages to the overlying skin and musculature
- Nasal spine
- Membranous septum

[a]On occasion, because of extreme anatomic variability, a "minor" tip support may assume the importance of one of the more major supports.

inspiration. This area corresponds intranasally to the internal valve area and may require reinforcement with graft such as alar batten grafts. In the normal state, this area is supported by the dilator naris and nasalis muscles (7). A second area is the alar margin, particularly lateral to the point at which the lateral crura diverge cephalically. In patients with projecting, thin noses, the alar margins are susceptible to collapse and resultant external valve narrowing.

In summary, the stability of the nasal skeleton derives from its rigid elements, the nasal bones, pyriform aperture, and nasal septum. The dynamic caudal structures, the nasal tip and base, are stabilized largely through the lower lateral crural attachments to these anchoring structures through networks of interconnecting fibrous tissue or ligaments. The means of support may be conceptualized both as a cantilevering mechanism from the nasal bones and ULCs cephalically and a pillar-like support from the septum ventrally. Although the inherent strength and resiliency of the LLCs create a dynamic tripod and provide form and some support to the nasal tip, a significant loss of tip support is incurred if the attachments of the tripod to the surrounding rigid structures are violated. In rhinoplasty, it is therefore imperative to reconstitute tip support through methods such as suture stabilization of the medial and intermediate crura to a stable midline foundation to prevent postoperative tip instability.

Variant Anatomy

The infinite variations of form are evident in the different structural orientations encountered in different noses. As Tardy reminds us, the relative role of any of the structural component of the nose differs from person to person. For example, individuals with long, broad nasal bones are more apt to have greater stability imparted to upper cartilaginous vault and to the caudal elements of the nasal tip and base. Within the tip itself, thicker, more developed cartilage provides greater strength and has a larger role in structural support than in someone with weak, thin cartilages. These differences are important to remember when choosing rhinoplasty techniques. For instance, one traditional method to decrease projection of the tip is simply to perform a full transfixion incision and an intercartilaginous incision. Because this incision violates many of the anchoring ligamentous attachments of the tip tripod, the nasal tip may settle toward the face, thus reducing overall projection. However, in a nose in which the medial crura are long and broad, their inherent strength and resiliency may prevent the tip from moving. Methods that reposition and fixate the tip structures to stable surrounding structures are more reliable, reducing the unpredictability of results based on patient-variant anatomy (1).

FUNCTIONAL VALVULAR ANATOMY

Internal Nasal Valve

The internal nasal valve area is the narrowest portion of the nasal passage. It is framed superolaterally by the caudal border of the ULC, medially by the septum, inferiorly by the floor of the pyriform aperture, and posteriorly by the head of the inferior turbinate (35). The *internal nasal valve*, formed by the caudal border of the ULC and the septum, is a specific slit-like structure within the internal nasal valve area and is often the narrowest region of the internal valve area. The angle formed by the attachment of the ULCs to the septum is 10 to 15 degrees in the Caucasian nose and wider in the African or Asian nose. If this angle is less than 10 degrees, the patient will likely experience nasal obstruction because of the collapse of the internal valve on inspiration.

External Nasal Valve

The external nasal valve consists of the nare and the nasal vestibule. The nasal vestibule is the space just inside the external nare and is the compartment caudal to the internal valve area. The vestibule is bordered medially by the septum and columella and laterally by the alar sidewalls. The vestibule contains vibrissae, or nasal hair, on a fold of skin under the lateral crus. Functioning as a coarse filter for inspired air, the vibrissae also serve a resistive purpose to slow the inspired air current and directing it posteriorly into the nasal cavity (36).

The internal and external nasal valves are dynamic structures that function together to deliver a smooth air current to the nasal cavities for humidification. During normal, quiet inspiration, the nasal valves change little in their cross-sectional areas. On deep inspiration, the nostrils flare to increase the diameter of the external valve. With

increased airflow, the intraluminal pressure in the internal valve area decreases according to the Bernoulli principle. The tendency for the valve to collapse, however, is counterbalanced by the resistance of its cartilaginous structure to deformation, as well as by isometric contraction of the alar dilator muscles to keep the lumen open. In normal nasal function, the cross-sectional area of the internal valve should be relatively unchanged during inspiration (37). Valvular collapse that occurs only during forced inspiration can be considered physiologic and does not usually require surgical correction (14).

Certain variants of normal nasal anatomy predispose people to nasal obstruction. Individuals with a narrow upper cartilaginous vault tend to have a more acute angle in the internal nasal valve and may be more susceptible to nasal obstruction, even in the resting state. Poiseuille's law states that the rate of air flow is directly proportional to the fourth power of the radius of the conduit. Therefore, even miniscule differences in airway size may have significant clinical effects. Individuals with weak ULCs or lateral nasal walls or both may have more collapse of the internal valve area during inspiration. Preexisting or traumatic septal deviation in the internal valve area also can narrow the valve and cause nasal obstruction. Collapse of the external valve on deep inspiration can result from insufficient support of the alar rim and alar lobule. Patients predisposed to such collapse have particular features that should alert the rhinoplasty surgeon: short nasal bones and a long upper cartilaginous vault (discussed earlier); narrow, projecting noses; slit-like nostrils; exaggerated supra-alar creases; visible pinching of the lateral wall with inspiration; thin cartilages and thin skin; and cephalically positioned lateral crura, which provide minimal support to the alar margins (38).

ETHNIC VARIATIONS

Three broad nasal morphology types have been used to describe ethnic variations. The *leptorrhine* ("tall and thin") nose is associated with Caucasian or Indo-European descent. The leptorrhine nose has served as the basis of aesthetic ideal in Western culture, and the specific nasal-analysis parameters associated with this ideal are discussed elsewhere in this textbook. Because it is the most extensively studied in modern nasal analysis, it also inevitably becomes the reference point for comparison when studying noses of different ethnicities. Only recently have non-Caucasian standards of nasal analysis been developed for specific ethnic groups.

The *platyrrhine* ("broad and flat") nose is associated with African descent. It is characterized by very thick skin, a low radix, a short dorsum, a bulbous and underprojected tip, and flared nostrils. An analysis of the African American female nose shows that compared with the Caucasian standard for nasal analysis, the columella-to-lobule ratio is decreased, and the alar width relative to the intercanthal distance is increased. With regard to the bulbous and underprojected tip, cadaver studies in African American males have demonstrated that the dimensions of the lateral crura are not significantly different from those of the Caucasian nose (39). However, the smallest cartilages were found among noses of the African subtype, and the largest were found in the Afro-Caucasian and Afro-Indian subtypes. This variability may underscore the effect of racial mingling on the canonic platyrrhine nose.

The *mesorrhine* ("intermediate") nose has features intermediate between the leptorrhine nose and the platyrrhine nose. The "typical" Asian or Latino nose is commonly regarded as mesorrhine, with a low radix, variable anterior dorsal projection, rounded and underprojected tip, and rounded nostrils. Note that considerable variation exists in this group. An individual from Northern China or Japan is likely to have a mesorrhine nose with strong leptorrhine characteristics, whereas another from Southeast Asia will likely share more platyrrhine features. In addition to differences in baseline characters, the types of nasal defects encountered in rhinoplasty may also depend on ethnicity. For example, Hispanic patients were more likely to have dorsal humps, saddle deformities, dependent alae, retracted columellae, and poor tip projection compared to Anglos (40).

Generalized characteristics of the canonic nasal morphology types are listed in Table 179.3 (41–43).

TABLE 179.3 GENERAL NASAL CHARACTERISTICS BY MORPHOLOGY

	Platyrrhine	Mesorrhine	Leptorrhine
Skin type	Very thick	Moderately thick	Thin
Dorsum	Short, wide, concave	Short, wide	Long, narrow
Radix	Low	Low	High
Nasal bones	Short	Short	Long
Nasal tip	Bulbous, underprojected	Rounded, underprojected	Projected
Columella	Short	Short	Long
Nasal alar width	Wide	Intermediate	Relatively narrow
Ala	Prominent flaring	Variable	Modest flaring

Any discussion of rhinoplasty for the "non-Caucasian nose" is by its nature flawed. It is overly simplistic to classify a non-Caucasian nose as an "ethnic" nose to which "ethnic rhinoplasty" principles apply. Two noses from two different ethnic backgrounds are likely to be as different from each other as they are from a Caucasian nose. In addition, as may be expected from studies of the Caucasian nose, significant variations in facial features are found within any given ethnic group, for example, as documented in African American women (44). Intragroup differences may be as great as intergroup differences. For instance, Latinos with Caribbean ancestry are more likely to have platyrrhine noses, whereas those of Central and South American descent have more leptorrhine noses (45). It would be incorrect to apply ethnic group characteristics blindly to an individual patient based on his or her background alone. Nevertheless, an awareness of the global differences between ethnic nasal morphologies will make a rhinoplasty surgeon more sensitive to the needs of all patients in preserving desired ethnic characteristics.

CONCLUSIONS

The nose is a dynamic and inconstant structure, its anatomy varying from individual to individual. The anatomic principles and support mechanisms described in this chapter are not intended to be inflexible rules applicable to all patients. Rather, they are meant to be guidelines with which any one individual's anatomy may be assessed to understand his or her tissue characteristics, structural dynamics, and anatomic features. Selection of the appropriate surgical techniques should begin with an accurate assessment of the individual anatomy. Only then will the rhinoplasty surgeon maximize the likelihood of achieving the intended aesthetic and functional result.

HIGHLIGHTS

- Altering the topographic dimensions of one region of the nose may have a significant visual impact on the appearance of another region.
- Modifications to the underlying nasal skeleton are less accurately transmitted through a thick SSTE, particularly when they are reductive. Even small contour changes or irregularities may transmit clearly through a thin SSTE.
- An inverse relation exists between the lengths of the nasal bones and upper cartilaginous vault. Long nasal bones provide greater stabilization to the ULCs and other caudal elements of the nose than do short nasal bones.
- The tremendous variation in the size, position, shape, and contour of the LLCs accounts for much of the diversity of nasal tip form and support.
- The structural support of the nose is provided by the osseous framework, nasal septum, and the ligamentous network that attaches the cartilaginous elements to these foundations and to each other.
- Certain anatomic variations predispose patients to destabilization and valvular insufficiency after rhinoplasty: short nasal bones, narrow projecting noses, deep supra-alar creases, inspiratory pinching of the lateral wall, and cephalic LLCs.
- An understanding of individual variant nasal anatomy and the features of nasal morphology that exist for different ethnicities allow the rhinoplasty surgeon to tailor treatment for each patient's unique needs.

Rhinoplasty: Incisions, Approaches and Analysis

180

Grant S. Gillman

A thorough and thoughtful approach to nasal analysis is the foundation upon which a successful aesthetic and functional rhinoplasty outcome is built. A consistent strategy—routinely applied—will hone one's analysis skills and minimize the likelihood of failing to address something that should have been recognized preoperatively. By studiously engaging in this practice preoperatively *and* postoperatively, one will come to better appreciate the dynamics of rhinoplasty and the anatomic and surgical correlates of one's observations and interventions.

No doubt, aesthetic ideals will vary—from patient to patient, from culture to culture, and from surgeon to surgeon (1–5). Nonetheless, the "guidelines" contained in this chapter are intended to serve as a useful, practical framework upon which to evaluate nasal aesthetics and from which to move forward to surgical planning.

ANATOMIC LANDMARKS

Familiarity with the nomenclature used for the reference points of surface anatomy facilitates improved communication between colleagues and clarity of notes and the operative record. In addition, knowing how underlying structures are reflected on the surface topography enables the surgeon to more accurately analyze, diagnose, and anticipate the pathology and thereby develop a more thoughtful surgical strategy preoperatively. Accordingly, it is appropriate to begin with terminology.

The commonly accepted terms for surface nasal anatomy, as seen from the frontal, lateral, and base views, are illustrated in Figures 180.1 to 180.3 and defined below. Nasal anatomy is also covered and reviewed in greater detail in the chapter on "Surgical Anatomy of the Nose."

Terminology

Trichion—the most anterior midline point on the hairline

Glabella—the most anterior or prominent point on the forehead (lateral view)

Nasion (aka radix)—the starting point, root, or visual takeoff of the nose, it is the deepest depression at the root of the nose in the midsagittal plane, corresponding to the nasofrontal suture. The midline junction between the frontal bone and the nasal dorsum is also known as the radix.

Rhinion—the midline junction of the nasal bones and the dorsal septum (osseocartilaginous junction)

Supratip—the point along the nasal dorsum that lies just cephalic to the nasal tip

Tip—the most anterior projecting part of the nasal profile (ideally). The tip "lobule" refers more broadly to the region bounded by the supratip superiorly, the anterior end of the alar crease laterally, and the anterior nostril margin posteroinferiorly.

Infratip lobule—the part of the nasal tip seen from the nasal base view that sits anterior to the columella and leading edge of the nares and extends to the tip-defining point

Soft tissue triangle (or soft tissue facet)—seen from the nasal base, this refers to the soft tissue skin fold that lies anterior to the apex of the nostril and just behind the caudal border of the junction of the medial and lateral crus of the lower lateral cartilage

Subnasale—midline junction of the columella and upper lip

Labrale superioris—the vermilion border of the upper lip

Stomion—the midline point at the junction of the upper and lower lips

Pogonion—the most anterior or prominent point on the chin (lateral view)

Menton—the lowest midline point on the chin

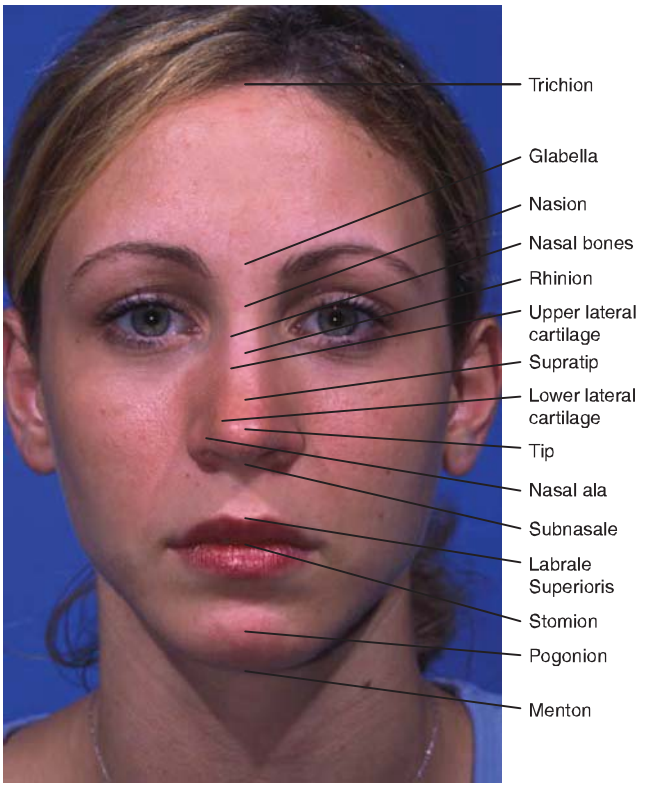

Figure 180.1 Surface anatomy nomenclature—frontal view.

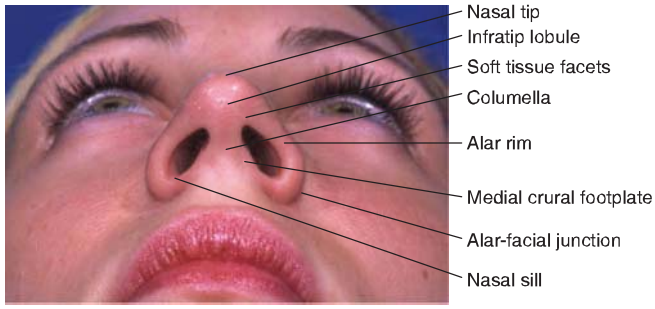

Figure 180.3 Surface anatomy nomenclature—base view.

NASAL AND FACIAL ANGLES

The most commonly referenced angles applied to nasal analysis are the nasofrontal angle, the nasofacial angle, and the nasolabial angle. Collectively these generate information on features that have some bearing on nasal–facial proportion such as tip rotation, tip projection, and nasal length, and they are very useful when evaluating the nasal profile.

The *nasofrontal angle* (Fig. 180.4) is the angle measured between a line extending from the glabella through the nasion and a second line drawn from the nasion through the nasal tip-defining point. The ideal nasofrontal angle ranges from 115 to 135 degrees. The deepest point of the nasofrontal angle is known as the nasion (or radix). Perhaps more important than the actual angle measurement itself, the position (superior vs. inferior) and depth of the nasofrontal angle and nasion have significant bearing

Figure 180.2 Surface anatomy nomenclature—lateral view.

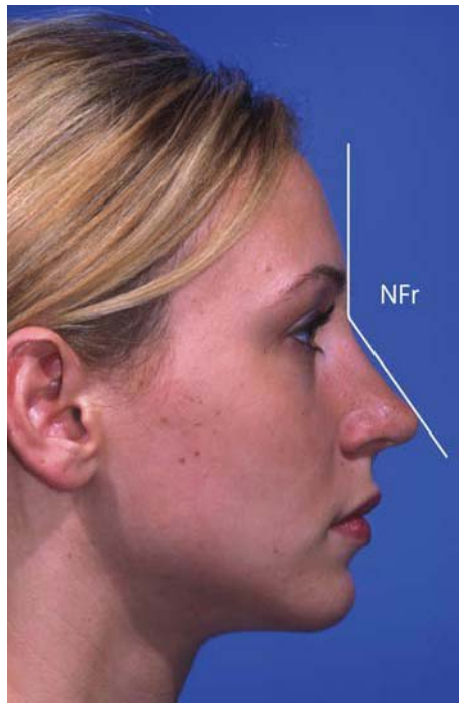

Figure 180.4 Nasofrontal angle—the normal angle measures 115 to 135 degrees.

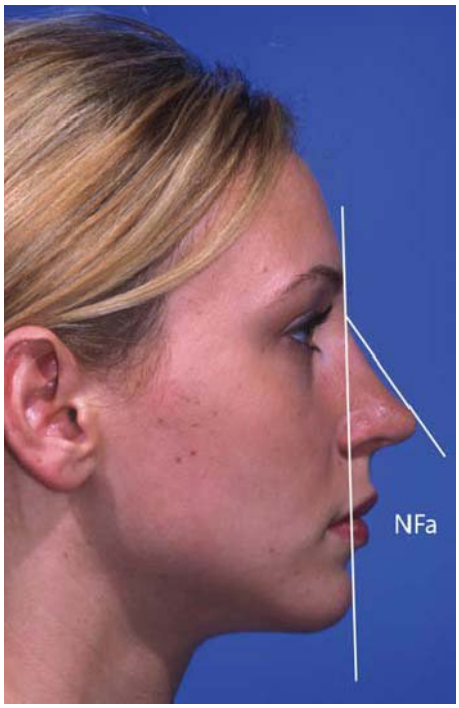

Figure 180.5 Nasofacial angle—the normal angle measures 30 to 40 degrees.

on the overall aesthetics and proportion of the nose as it relates to the rest of the face. This is discussed in greater detail in the section on nasal analysis.

The *nasofacial angle* (Fig. 180.5) is formed by a line from the glabella through the pogonion, intersecting with a line from the nasion through the nasal tip-defining point. The ideal nasofacial angle ranges from 30 to 40 degrees (ideal 36 degrees). A larger (more obtuse) angle reflects a relative increase in tip projection whereas the nasal tip would appear less projected with a more acute nasofacial angle.

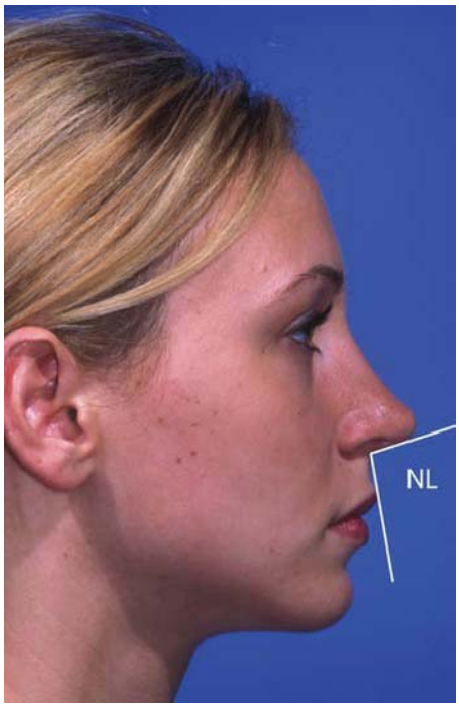

Figure 180.6 Nasolabial angle—the normal angle measures 90 to 115 degrees.

The *nasolabial angle* (Fig. 180.6) is the angle formed between the upper lip (from subnasale to labrale superioris) and the plane of the columella through the subnasale. The ideal nasolabial angle ranges from 90 to 115 degrees. Males typically have a more acute nasolabial angle (90 to 105 degrees) consistent with less tip rotation, while the ideal nasolabial angle in females ranges from 100 to 115 degrees in keeping with more tip rotation.

SURGICAL INCISIONS AND APPROACHES

An important distinction is made between surgical *approaches* and *incisions*.

A surgical *approach* refers to the means of exposing the structures of interest. The approach that is chosen will then dictate the *incisions* that are used to enable that approach. The surgical approach chosen for nasal surgery will vary with the training, comfort level, experience, and preference of the operating surgeon as well as the complexity of the case. While there are a variety of surgical approaches and the preferred approach may vary from surgeon to surgeon, as a general rule, the more severe or complicated the nasal deformity in question, the more likely the surgeon is to benefit from broader exposure.

Surgical approaches can be broadly categorized into *external* or *endonasal* approaches. Endonasal approaches can be subdivided into approaches to the nasal dorsum, the nasal septum, or the nasal tip, and endonasal tip approaches can then be further divided into delivery and non-delivery approaches (Fig. 180.7).

Although no absolute indication exists for either an external or endonasal approach and multiple factors will play into the choice of the operating surgeon as noted earlier, a reasonable set of guidelines for each, which may be of benefit to the less experienced surgeon, is outlined in Table 180.1.

Incisions

Surgical incisions are made to facilitate surgical exposure, but the incisions in and of themselves, properly made, have little or no impact on the ultimate dorsal contour, tip shape, or septal position. The surgical incisions most commonly used or referred to in the literature include

- The *marginal* (aka infracartilaginous) incision (Fig. 180.8)—an incision of variable length made along the caudal margin of the lower lateral cartilage. It may be along the caudal border of the lateral crus only in certain

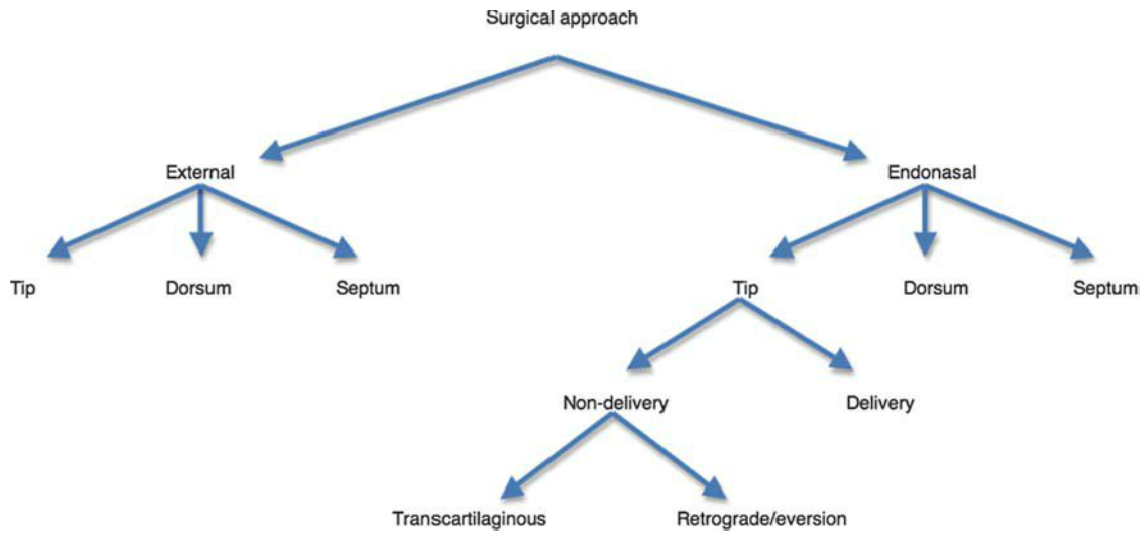

Figure 180.7 Surgical approaches to the nose.

circumstances, the medial crus only, or along the entire caudal edge of the lateral crus.

- The *transcolumellar* incision (Fig. 180.8)—an incision made transversely across the short axis (width) of the columella, joining bilateral marginal incisions at its lateral end to facilitate the external approach to the nose. It is typically sited over the medial crura about midway back along the columella and is generally irregularized (nonlinear) in some fashion for better camouflage and less scar contracture.
- The *intercartilaginous* incision (Fig. 180.8)—an incision made at the junction of the caudal border of the upper lateral cartilage and the cephalic border of the lower lateral cartilage (hence "inter"-cartilaginous). Alone it can provide access to the upper two-thirds of the nasal vault (bony and cartilaginous dorsum, nasal sidewall) as well as retrograde access to the lateral crura of the lower lateral cartilages. When combined with marginal incisions, it allows the surgeon to release and "deliver" the lower lateral cartilage as a bipedicled chondrocutaneous flap, pivoting inferiorly in a bucket-handle fashion to enable tip contouring in endonasal rhinoplasty using a delivery approach.
- The *rim* incision—an incision placed just within the nasal vestibule along the rim of the nostril margin. Owing to its proximity to the rim of the nares, any untoward healing or scar contracture with this incision carries a higher risk of visibility, retraction, notching, or irregularity along the alar margin as compared to a marginal incision, and as such, it has fallen out of favor and is less frequently used.
- The *transcartilaginous* (or cartilage-splitting) incision (Fig. 180.8)—an incision made through the lateral crus of the lower lateral cartilage caudal to the junction of the upper and lower lateral cartilage and at least 5 to 6 mm above the caudal margin of the lateral crus of the lower lateral cartilage. Effectively this divides the lateral crus into a superior (cephalic) and inferior (caudal) segment enabling removal of the cephalic strip for volume reduction of the tip cartilage.

TABLE 180.1 GUIDELINES FOR SELECTION OF SURGICAL APPROACH

Endonasal Rhinoplasty	External Approach Rhinoplasty
• Dorsal reduction — Modest reduction, nasal bones of normal length (*not* short nasal bones with long upper lateral cartilages) — Normal width and alignment of middle third of nasal vault • Tip surgery — Primary (non-revision) surgery — To modify tip definition (boxy, wide, bifid, broad/bulbous tip) — No gross asymmetry — Modest increase/decrease in tip projection — Limited tip revision surgery • Linear deviation of nasal dorsum in need of osteotomies	• Congenital nasal deformities, for example, cleft lip rhinoplasty • Major dorsal reduction or dorsal reduction with narrow/pinched middle third of nasal vault • Major change in tip projection • Marked nasal septal deformities • Twisted nose • Need for sutured-in-place structural grafting (middle nasal vault or lower third) • Very thick skin • Large septal perforation for repair • Major secondary (revision) surgery

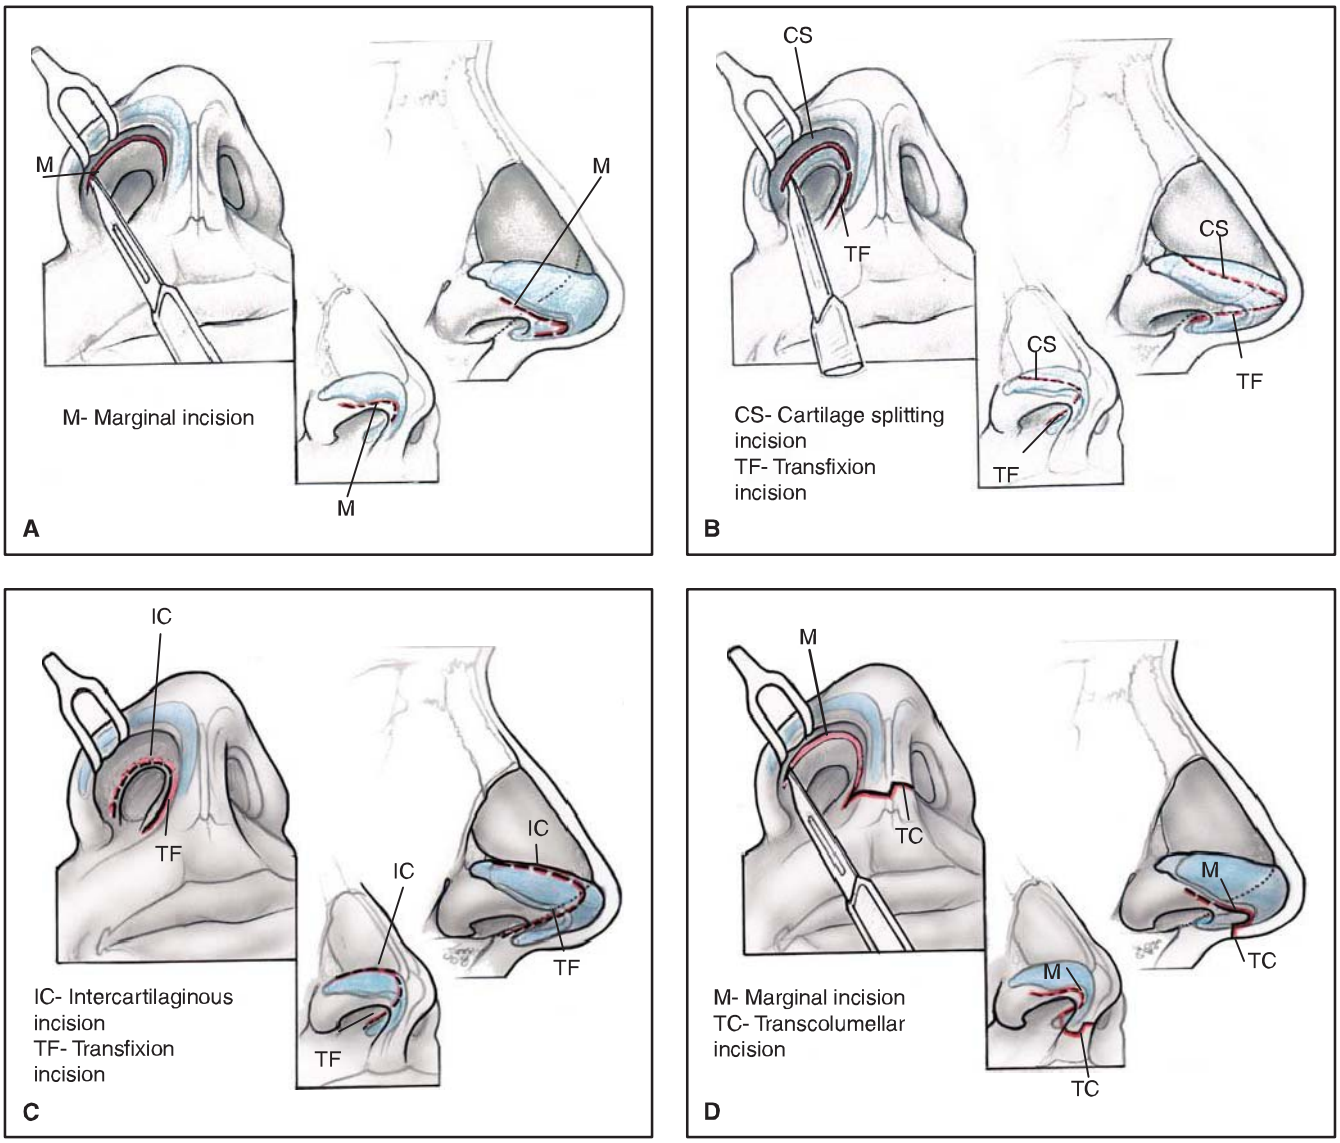

Figure 180.8 Nasal-tip incisions. **A:** Marginal incision. **B:** Cartilage splitting (trans-cartilaginous) incision and transfixion incision. **C:** Inter-cartilaginous and transfixion incision. **D:** Transcolumellar and marginal incisions.

- The *hemitransfixion* incision (Fig. 180.9)—an incision made unilaterally in the membranous septum at or just below the caudal edge of the septum. This allows access to one or both sides of the nasal septum and when combined with either an intercartilaginous or transcartilaginous incision dissection can facilitate exposure of the nasal dorsum right up to the nasion.
- The *full transfixion* incision—an incision completely across the membranous septum from one side of the nasal vestibule to the other, just below the caudal edge of the septum. This incision separates the attachment of the medial crural feet from the caudal septum. Like the hemitransfixion incision, the complete transfixion incision enables access to either side of the septum, the anterior nasal spine, and the depressor septi muscle. It may be made alone or as a continuation of either an intercartilaginous incision (to facilitate alar delivery in combination with bilateral marginal incisions or for dissection along the nasal dorsum) or a transcartilaginous incision (to facilitate dissection along the nasal dorsum).
- The *Killian* incision (Fig. 180.9)—this incision is made through septal mucoperichondrium parallel and approximately 4 to 5 mm cephalic to the location of a hemitransfixion incision, further up in the nose proximal to the mucocutaneous junction. It is primarily a septal access incision. By virtue of its location, this incision preserves the mucosal attachment and blood supply to the most caudal aspect of the nasal septum. For septal deflections requiring modification of the caudal septum, either a hemitransfixion incision or external approach to the septum (depending on the severity of the problem) is preferred over the Killian incision.

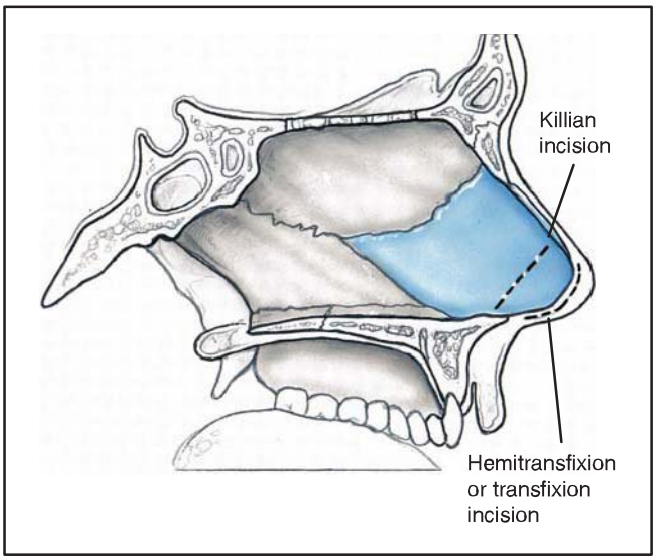

Figure 180.9 Nasal septal access incisions.

Approaches

As regards surgical approaches to the nose, the *external approach* combines bilateral marginal incisions with a transcolumellar incision as noted earlier. Dissection and elevation of the skin and soft tissue envelope can then continue in a cephalad direction right up to the nasion if need be. The primary advantage of the external approach is unparalleled exposure and the unlimited ability to modify the cartilages as need be. Optimal visualization can be particularly beneficial in circumstances where the underlying anatomy is unclear such as revision surgery or patients with gross asymmetry and provides a definite advantage when sutured-in-place cartilage grafting is desired.

Potential disadvantages of the external approach include the extent of dissection and therefore surgical trauma in situations where more limited dissection might suffice. Wider undermining with the external approach generally translates into more postoperative edema that persists longer than in the typical endonasal rhinoplasty. In circumstances where one can comfortably achieve the same or similar result through a less invasive approach, the attendant reduction in tissue trauma is desirable. Routine disruption of native cartilaginous attachments to skin may not always be necessary. Greater ligamentous disruption and skin undermining may in fact result in a greater loss of tip projection when compared to similarly applied techniques using an endonasal approach (6), thereby necessitating maneuvers to restore or reestablish tip projection. Finally, it must be said that greater exposure alone does not equate with better surgical results—failure to apply thoughtful, assiduous analysis and meticulous surgical technique will not be overcome merely by enhancing exposure.

There are a number of endonasal approaches to the nose. A *retrograde approach* utilizes an intercartilaginous incision for retrograde access to the lateral crura of the lower lateral cartilages, thereby enabling a conservative volume reduction of the cephalic portion of the lateral crus. The *transcartilaginous approach* uses a cartilage-splitting incision for removal of a predetermined amount of the cephalic portion of the lateral crus (that portion superior to where the incision is made). Like the retrograde approach, the transcartilaginous procedure has limited application, being primarily used for very moderate volume reduction of a tip which is otherwise well structured. The disadvantages of both of these two approaches are the limited ability to otherwise modify the cartilage beyond a cephalic trim, limited access to the domal area of the lower lateral cartilages, and therefore the inherent difficulty of insuring symmetry between the two sides.

The *delivery approach* is the most versatile of the endonasal approaches to the nasal tip. By using a marginal incision and an intercartilaginous incision connected to a full transfixion incision, surgical dissection will release the superior and inferior attachments of the lower lateral cartilage while maintaining attachments medially and laterally. It can thus be pivoted caudally, in a bucket-handle fashion so as to "deliver" a bipedicled chondrocutaneous flap. Broader exposure and more direct visualization of the lower lateral cartilages permits a greater range of surgical modifications to be applied than with either the retrograde or cartilage-splitting endonasal approaches. The main disadvantage with the delivery technique as compared to an external approach is the disruption or distortion of native *in situ* relationships between the lower lateral cartilages when delivered and greater technical difficulty with certain cartilage grafting techniques.

NASAL ANALYSIS

It is impossible to overstate the value of assiduous and systematic nasal analysis. Rhinoplasty surgeons may differ in terms of their own aesthetic ideal, their preferred surgical approach, instrumentation, dressings, postoperative care—in short, they may differ in almost every surgical sense. Except the value that they place on thoughtful preoperative analysis. On that they would all agree—careful and thorough preoperative analysis will promote better and more consistent outcomes, reduce revision rates, and minimize the traps that await oversight and errors of omission. Nasal surgery is not a good place for 20-20 hindsight.

Uniform and reproducible photographs are a fundamental part of the evaluation process and surgical planning, in addition to being an accurate reminder of the preoperative state. Images of consistent size, quality, lighting and positioning will facilitate an honest and accurate appraisal of postoperative changes as compared to the preoperative views. A more detailed discussion of the technical aspects of photo documentation is covered in Chapter 171 of this text.

The standard views for rhinoplasty are vertically oriented full face frontal, right and left oblique, right and left lateral views, and a base view (horizontally or vertically oriented).

Optional views include the frontal close-up (to highlight particular asymmetries or a crooked nose), a "bird's eye" or dorsal view (for a crooked nose), and a lateral smiling view (to highlight the activity of the depressor septi muscle). A lateral view with a ruler alongside the patient's face can be helpful to enable one to make life-size reproductions, which then allow for accurate preoperative measurements to be made.

All parts of the physical examination, inspection, and palpation should impart meaningful information to the examiner at each and every step. For the skilled clinician, an impressive amount of information relevant to treatment (medical or surgical) can be gleaned in only a few minutes.

Evaluation of the rhinoplasty patient begins with an overall survey of facial proportion and symmetry. Naturally there will be some variation in anthropometric norms from one race to another as alluded to earlier. The typical occidental Caucasian face can be roughly divided into equal horizontal thirds (Fig. 180.10)—from the hairline (trichion) to the glabella, from the glabella to the subnasale, and from the subnasale to the menton (chin). As there is great variability in hairline position, another way of looking at nasal and facial proportion considers the distance from the nasion to the menton (Fig. 180.11). Using this method, a nose which is in relatively good proportion to the face as measured from nasion to subnasale, is 43% of the nasion–menton distance,

Figure 180.10 Facial proportion—the face can be roughly divided into equal horizontal thirds, from trichion (hairline) to glabella, glabella to subnasale, and subnasale to menton.

Figure 180.11 Facial proportion—lower facial two-thirds—the distance from nasion–subnasale is 43% of total nasion–menton distance, whereas the subnasale–menton distance is 57% of the total.

whereas the measurement from subnasale to menton is 57% of the total distance. The nasion-to-subnasale measurement is therefore three-fourths of the subnasale-to-menton distance. The face may also be divided into vertical fifths (Fig. 180.12), each of which equals the intercanthal distance (between medial canthi) or the width of the palpebral fissure (from medial to lateral canthus).

After an overall survey of facial proportion and symmetry is complete, inspection of the nose is carried out next from a frontal, lateral, and a base view, at rest and with normal inspiration. Any tendency of the lateral nasal wall or nasal ala to medialize or collapse on mild to moderate inspiration should be noted. Dynamic collapse of the nasal sidewall suggests instability or lack of proper structural support in that region, which should be addressed at the time of surgery.

Proper endonasal inspection of the nasal airway with a headlight and speculum further complements the information acquired from visual assessment of inspiratory stability. Ideally an endoscopic exam completes a physical examination of the nasal airway. At this point, the examiner should have a good sense of septal alignment, turbinate size, and width of the nasal valve angle (normal = 10 to 15 degrees).

Palpation of the nose follows. This gives the surgeon an indication of the thickness of the nasal skin, the presence of any palpable ridges or irregularities, the length of the

Figure 180.12 Facial proportion—the face can be divided into vertical fifths, each approximately equal to the intercanthal distance or the width of the palpebral fissure.

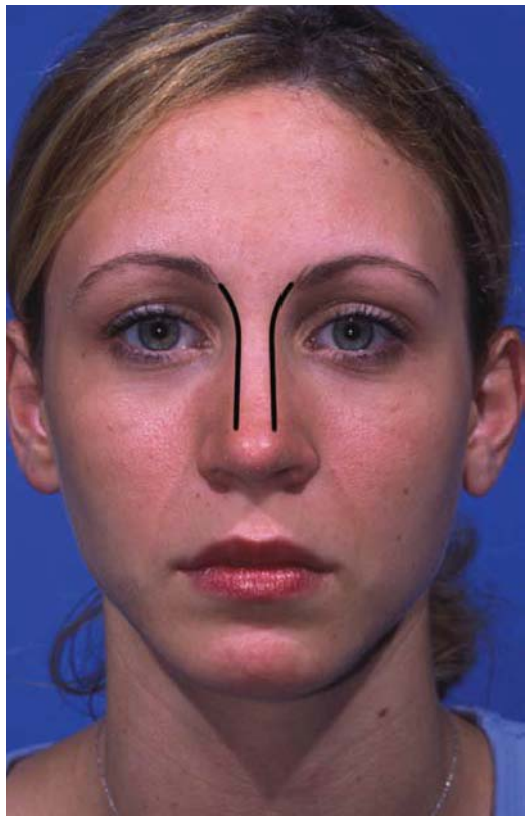

Figure 180.13 The brow–tip aesthetic lines outline the nasal dorsum.

nasal bones relative to the upper lateral cartilages along the nasal dorsum, and some sense of the intrinsic strength of the alar cartilages, tip support, and caudal septum.

Assessment is then carried out by examining the nose from a frontal view, oblique and lateral views, and base view.

On the *frontal* view the examiner should evaluate

- Overall symmetry. Asymmetries should be pointed out to the patient preoperatively.
- Alignment (straight or crooked) and where if any misalignment exists (upper one-third, middle one-third, and/or lower one-third). Problems with alignment might suggest the need for osteotomies, rasping, onlay grafts, spreader grafts, or nasal tip surgery depending on where the asymmetry is centered. This is further discussed in the chapters on tip surgery and the management of the crooked nose. Narrowing of the middle nasal vault in particular is important to recognize since medialization of the upper lateral cartilage in this region will increase airflow resistance through the internal nasal valve and may account for a functional problem that would merit spreader grafting.
- Tip definition and visible highlights or irregularities
- Width of the bony nasal pyramid (upper one-third of the nose) as well as that of the nasal base. The alar base width should fall within lines dropped from each medial canthus. The bony width should be about 75% to 80% of alar base width.
- The brow–tip aesthetic lines (Fig. 180.13)—paired, smooth, gently curving lines, which follow the curvature of the brow, continuing caudally down the lateral nasal dorsum (at the junction of the dorsum and nasal sidewall) to the tip-defining points. Deviations along this line may be seen in patients with prior trauma and crooked or twisted noses as well as in those with pinching or narrowing in the middle third of the nose where the upper lateral cartilages fuse with the dorsal septum (the internal nasal valve region).

On the *oblique* view, one should evaluate

- The brow–tip aesthetic line. The left oblique view highlights the right brow–tip line and vice versa. Often irregularities along this line are well appreciated on the oblique view.
- The height of the nasal dorsum
- Soft tissue facets

A substantial amount of information is revealed from examination of the nose in *lateral* view. Owing to the volume and complexity of what is seen from this view of the nose, it is helpful and therefore recommended to proceed in a methodical and reproducible fashion each and every time. In that respect, the author recommends first taking a broader view of the nose and how it relates to overall facial proportion and then proceeding sequentially from nasion

to subnasale. In this way, one can avoid overlooking features of interest or import. Specifically, on the *lateral* view beginning at the root of the nose and moving caudally, one should evaluate

- Radix position, radix projection, and nasofrontal angle. The ideal radix position or visual radix breakpoint should lie around the level of the supratarsal crease or between the crease and the upper eyelid margin. This will influence the height of the nose from nasion to subnasale, which should roughly equal 43% of the distance from nasion to menton. If the nasion or visual takeoff of the nose is low (a caudally positioned radix—often referred to as "low radix disproportion"), the nose will look shorter, the tip will appear to be relatively overprojected (a "bottom-heavy nose"), and the dorsal height will be somewhat exaggerated (Fig. 180.14), whereas the opposite is true when the radix is cephalically malpositioned ("high radix disproportion"). Regarding radix projection, Byrd calculates the normal radix projection to be 0.28 × ideal tip projection (see calculation under tip projection), which generally corresponds to 9 to 14 mm from the anterior corneal plane (7). An underprojected radix (deep radix) will exaggerate any apparent dorsal height and may create the illusion of a "pseudohump" when dorsal height might be appropriate (8). In addition, a deep radix, much like a low radix, will make the nose look shorter and the tip look relatively overprojected while an overprojected (shallow) radix will make the nose look longer and the tip less projected. A deep or low nasofrontal angle (deep or low radix) might warrant the need for radix grafting to bring the radix forward or higher and to improve upon relative proportions of the nose.
- The length of the nose, from radix to the most anterior projecting point on the tip. Byrd's dimensional analysis (7) derives ideal nasal length from measurements taken from either the midface or lower face. Midfacial height (MFH) is the measured distance from the glabella to the alar base plane (a transverse line through the alar base, perpendicular to the vertical axis of the face). Using his method, ideal nasal length is two-thirds of MFH (using midfacial measurements), or equal to the distance from the stomion to the menton (using lower facial measurements). When the mandible is underdeveloped (e.g., microgenia), the midfacial guideline is preferred.
- The height of the nasal dorsum and whether it be in need of reduction, augmentation, or neither. Height of the nasal dorsum, or lack thereof, is clearly considered relative to the radix depth and nasal-tip projection. With appropriate radix position and depth, if one were to draw a line from the nasion to the tip-defining point, the height of the dorsum would either be level with that line (male) or 1 to 2 mm below that line (female) conferring a slight supratip break so that the leading point of the nose is the tip and not the dorsum.
- The presence or absence of a supratip break (seen when the tip projects just slightly anterior to the dorsal line in the lateral view)
- Nasal tip projection. There are several methods to assess tip projection. Byrd calculates that ideal tip projection, measuring from the alar cheek junction to the anteriormost point on the tip, is two-thirds of ideal nasal length (as calculated above) (7). Crumley describes the nose as a right angle triangle with a 3:4:5 ratio, whereby nasal-tip projection is 60% (three-fifths) of nasal length from nasion to tip-defining point (9) (Fig. 180.15). Goode draws a vertical line from the nasion through the

Figure 180.14 Low radix disproportion—a deep or caudally positioned radix (*arrow*) as seen preoperatively on left will make the nose appear shorter, the tip appear relatively overprojected, and the dorsal height appear exaggerated. Postoperatively on right, after radix augmentation with only conservative dorsal reduction, the radix takeoff has been moved cephalically and the nose looks better balanced and proportionate.

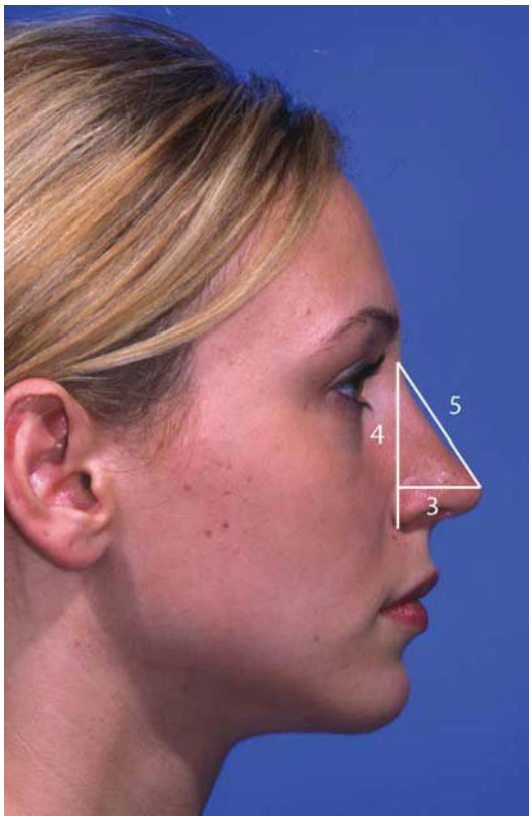

Figure 180.15 Crumley's 3:4:5 right angle triangle estimates appropriate tip projection to equal three-fifths (60%) of nasion-to-tip distance. Goode's calculations yield similar proportions.

alar cheek junction and a second line perpendicular to the first running from the alar facial junction to the nasal tip. Using his technique, this second line, which reflects tip projection, is 0.55 to 0.60 × nasion-to-tip distance (nasal length) (10). These lines essentially recreate the same 3:4:5 right angle triangle described by Crumley.

- The columellar double break—a slight change in plane along the nasal base at the transition point from the columella to the infratip lobule at the anterior nares
- The alar–columellar relationship. Normal columellar show as measured on lateral view from the highest point on the curved alar rim to the lower edge of the columella is 2 to 4 mm. Values in excess of that may be due to an overly long caudal septum, bowing of the medial crura or alar retraction. Measurements below 2 mm can be due to a retruded columella, foreshortened caudal septum or alar hooding (11).
- Tip rotation or the nasolabial angle. The ideal range is approximately 90 to 115 degrees, with men being generally more acute and women being more obtuse.
- Chin position. In men, the most anterior point of the chin (the pogonion) should lie at or just anterior to a vertical line dropped from the vermilion border of the lower lip, whereas in women the pogonion should be at or just behind that line. With obvious microgenia, a discussion of chin augmentation or advancement genioplasty is warranted to optimize overall facial balance.

On the *base* view, the examiner should evaluate

- Symmetry. Are there visible irregularities of the tip cartilages? Are the nostrils symmetric?
- Shape of the nasal base. Is it nicely triangular (isosceles) or boxy, broad, amorphous, trapezoidal, etc.?
- Bifidity (separation) of the alar domes
- Contour of the alar sidewall. Is the alar sidewall straight or slightly convex and stable, or is there any buckling/concavity of the lateral crura or alar collapse, either at rest or with inspiration (suggestive of external nasal valve compromise)?
- The position of the caudal septum
- The columella-to-lobule ratio. Ideally 2:1
- Width of the alar base

CONCLUSION

Fluency with the nomenclature, understanding the utility of the various nasal incisions and merit of different surgical approaches and having a consistent framework to apply to nasal analysis are the essential starting points for the rhinoplasty surgeon, and this chapter is intended to serve as a useful resource in that regard.

It has been said that diagnosis precedes technique. As one of the most challenging, humbling and variable procedures in facial plastic surgery, successful rhinoplasty is heavily predicated upon accurate preoperative assessment and diagnosis. It is thus incumbent upon the rhinoplasty surgeon to develop a dependable, thorough and reproducible approach to nasal analysis. In this way, more consistently successful results and greater levels of patient and surgeon satisfaction are assured.

HIGHLIGHTS

- Thoughtful, systematic and precise preoperative nasal analysis is the foundation of a well-planned and well-executed rhinoplasty.
- Fluency with proper terminology and nomenclature enables better record keeping and clearer communication between colleagues.
- Racial and anthropometric "norms" account for differences in "ideal" facial and nasal proportions and characteristics.
- Surgical approaches to the nose should be chosen based on experience, the surgical plan and complexity of the case. The goal is always maximal results with minimal surgical intervention. Once chosen, the surgical approach guides the selection of incisions.
- Each preoperative photograph conveys specific information—knowing what to look for and how to study each image is a vital skill to acquire for anyone performing rhinoplasty surgery.

181 The Nasal Dorsum: Management of the Upper Two-Thirds of the Nose

Randolph B. Capone *Ira D. Papel*

Of all the aesthetic facial units, the nose plays a predominant role in facial proportion and harmony. As a single unpaired structure occupying the midface, it serves to balance the facial thirds and fifths as well as those aesthetic units surrounding it. Seemingly small changes after rhinoplasty or traumatic injury frequently effect dramatic changes in nasal appearance. The nose is not, however, only an aesthetic structure but also a respiratory and olfactory organ. This duality of nasal form and function mandates that rhinoplasty must enhance nasal appearance and optimize the nasal airway. It is essential, therefore, that the nasal surgeon have a detailed understanding of nasal anatomy and physiology and a thorough grasp of the many interventions available in rhinoplasty. In this chapter, we discuss these issues with regard to management of the upper two-thirds of the nose, that is, the bony and cartilaginous vaults.

ANATOMY

The upper two-thirds of the nose contains the dorsum and sidewall aesthetic subunits, whereas the tip, columella, soft tissue triangles, and alae constitute the lower third of the nose (Fig. 181.1) (1). Topographically, the upper two-thirds of the nose is that portion from the *nasion* to the level of the alar groove (Fig. 181.2), where the nasion is defined as the intersection of the internasal suture with the nasofrontal suture in the midsagittal plane. The *radix* is the root of the nose and defines the most posterior point along the curve from the glabella to the nasal dorsum.

Skin and Subcutaneous Tissue

The skin overlying the upper nasal two-thirds has variable thickness. Relatively thick at the nasion (2 to 5 mm), it becomes thin and mobile over the dorsum (3.2 mm) and thinnest at the rhinion (2 to 2.2 mm) and gradually thickens again, becoming sebaceous toward the tip (5 mm) (2). This variability is important in planning the dorsal profile because creation of a straight skeletal profile will not likely create a straight postoperative profile. When edema diminishes, the surgeon may find that the rhinion has been overresected if no allowance for skin thickness was considered during surgery.

Beneath the skin is a thin fibrous layer designated the nasal superficial musculoaponeurotic system (SMAS) (3). Analogous to the facial SMAS, the nasal SMAS encompasses the nasal musculature and is located immediately superficial to the periosteum and perichondrium. Dissection just below the nasal SMAS provides a less traumatic and easier dissection plane during rhinoplasty, with preservation of nasal vasculature, nerves, and lymphatics that lie within the skin–soft tissue envelope (4).

Nasal Bones and Upper Lateral Cartilages

Deep to the nasal SMAS are the paired nasal bones and upper lateral cartilages. The nasal bones fuse with the frontal bone approximately 11 mm superior to the intercanthal line and are on average 2.5 cm in length (5). The length can be quite variable and represents a significant risk factor for airway compromise after rhinoplasty, for the shorter the nasal bones, the greater the proportion of cartilaginous nasal anatomy that is cantilevered and supported (6). The caudal margin of the nasal bones overlaps the cephalic margin of the upper lateral cartilages, which in turn interlock with the paired lower lateral cartilages at the *scroll* (Fig. 181.3). Each of these connections is an important structural component that contributes to nasal integrity and support.

Laterally, the caudal margin of the nasal bones and the anterior margin of the ascending processes of the maxilla form the *piriform aperture*. The lateral margin of the upper lateral cartilages fuses with dense connective tissue, and the

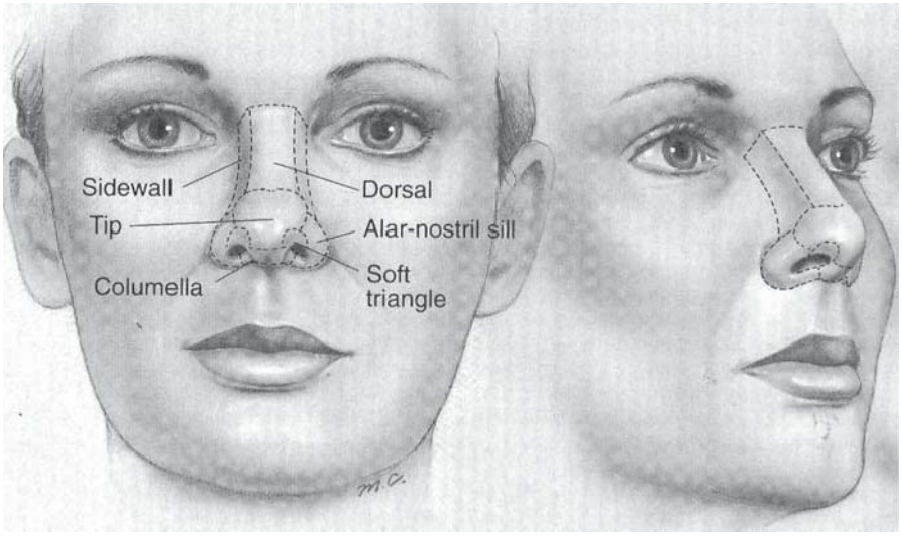

Figure 181.1 Nasal aesthetic subunits. (From Burget GC, Menick FJ. *Aesthetic reconstruction of the nose.* St. Louis, MO: Mosby, 1994:7, with permission.)

medial margin fuses with the septum superiorly but separates and is mobile inferiorly. Mucosa is tightly adherent to the internal surface of the cartilages and is continuous with the lining of the septum and lateral nasal wall.

The caudal margin of the upper lateral cartilage, the anterior head of the inferior turbinate, the proximate septum, and floor of the nose define the borders of the *internal nasal valve*. The angle between the upper lateral cartilages and the septum is the *nasal valve angle*, normally 10 to 20 degrees. The internal nasal valve typically has a cross-sectional area of 55 to 83 mm^2 and represents the site of greatest nasal resistance. It is the primary airflow-limiting segment of the nasal cavity in the human nose (7).

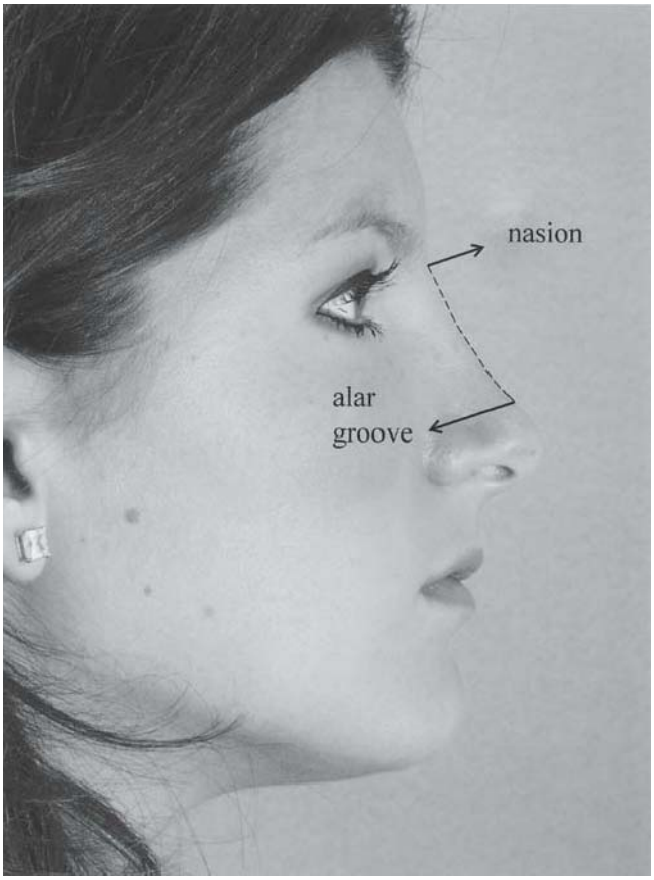

Figure 181.2 Upper nasal two-thirds: nasion to alar groove.

The Bony and Cartilaginous Vaults

The upper nasal two-thirds can be thought of as two contiguous arches, or vaults—a superior *bony vault* and an inferior *cartilaginous vault*. The nasal bones and the paired ascending processes of the maxilla comprise the bony vault, and the cartilaginous vault is composed of the upper lateral cartilages and the cartilaginous dorsal septum. The region of transition of the bony vault to the cartilaginous vault is known as the *rhinion*. The soft tissue linkage that occurs at the rhinion is comprised of upper lateral cartilage perichondrium that inserts on the undersurface of the paired nasal bones. This union allows for motion of the inferior vault relative to the superior vault.

As the name implies, nasal vaults are critical for support, distribution of forces, maintenance of dorsal height, and maintenance of nasal projection. As with any arch, the most essential support element occurs at the keystone. The nasal *keystone area* is the convergence of the caudal margin of the nasal bones, the perpendicular plate of the ethmoid bone, the cephalic margin of the upper lateral cartilages, and the cartilaginous septum. Understanding this area is critical during planning and execution of osteotomies so as to effect a change without disruption of important support mechanisms.

NASAL ANALYSIS

The face is a complex set of surfaces with tremendous variability. The goal of facial analysis is to provide a consistent framework to compare pre- and postoperative results despite this variability. Nowhere is this more important

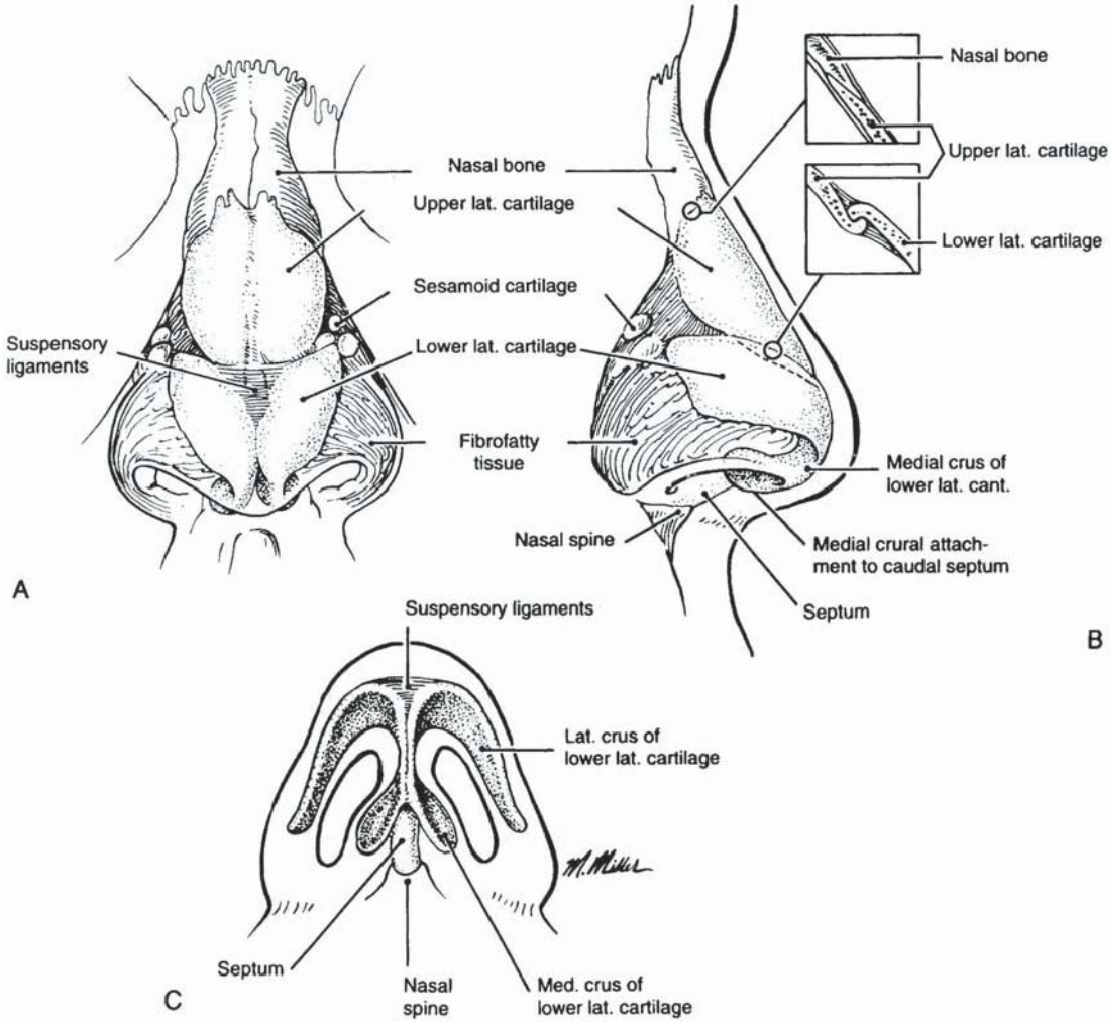

Figure 181.3 Anatomic relationships of the nasal bones, upper lateral cartilages, and lower lateral cartilages. (Modified from Papel ID. Management of the middle vault. In: Papel ID, ed. *Facial plastic and reconstructive surgery*, 2nd ed. Stuttgart, Germany: Thieme, 2002:408, with permission.)

than in rhinoplasty. Every rhinoplasty candidate should have high-quality six-view photography to facilitate analysis. In addition, an additional chin-down view is especially useful in evaluation of patients with nasal vault deformity (Fig. 181.4).

Aesthetic Angles

Analysis of the nasal aesthetic angles reveals the importance of the dorsum in evaluation of the rhinoplasty patient. Of the five facial aesthetic angles, three are determined using the geometry of the nasal dorsum: the nasofacial, the nasofrontal, and the nasomental angles. The *nasofacial angle* is the angle prescribed by the intersection of the facial plane (glabella to pogonion) and a line tangent to the nasal dorsum. Ideally, it is 36 to 40 degrees. The *nasofrontal angle* is determined by the intersection of the line connecting the nasion and glabella and the nasal dorsum tangent, ideally 115 to 130 degrees. Lastly, the *nasomental angle* is determined by the intersection of the line connecting the tip-defining point to the pogonion and the nasal dorsum tangent. The ideal nasomental angle is 120 to 132 degrees. Each of these angles should be carefully considered during the examination and photographic evaluation of the rhinoplasty candidate.

Nasal Length

Leonardo da Vinci introduced the practice of dividing the face into equal vertical thirds and horizontal fifths for the purpose of facial analysis. Later modified by Powell and Humphreys (8), this serves as the basis for modern-day facial analysis. A method more specific to nasal analysis, however, divides the lower face into two parts using the nasion, subnasale, and menton as landmarks (9). Using this method, nasal length (nasion to subnasale) should be three-fourths the distance from the subnasale to the menton (Fig. 181.5).

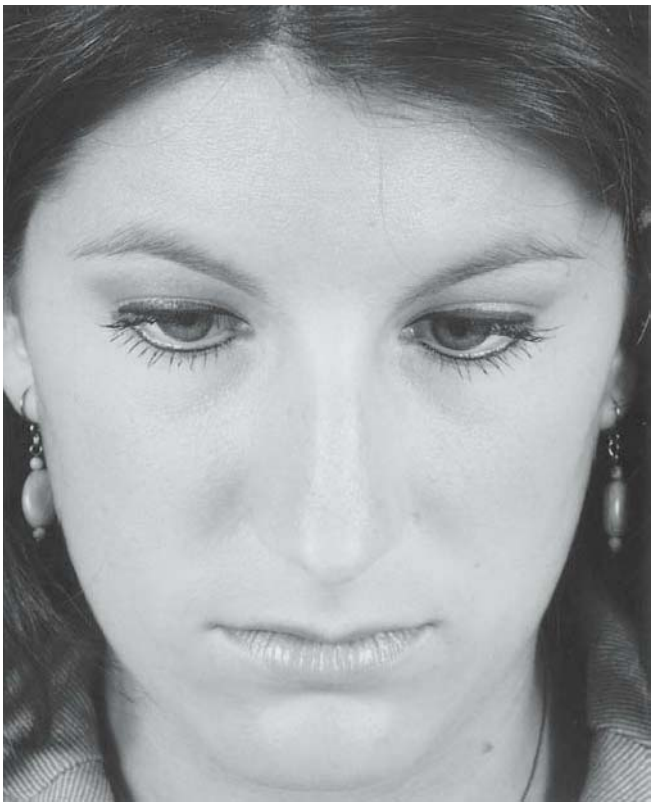

Figure 181.4 The chin-down view of nasal dorsum is useful to detect the presence of subtle radix contour irregularities or asymmetry.

Nasal Width and Radix Contours

On frontal view, nasal width should increase along its length, with a minima occurring at the intercanthal line. Maximal nasal width occurs at the alae and should equal one-fifth the width of the face. The upper nasal contour should follow a gentle curve from the medial eyebrow to the ipsilateral tip-defining point. Any irregularities in this *brow–tip aesthetic line* will quickly be noted as different from the contralateral side, thereby contributing to asymmetry and an unsightly appearance. The pair of these lines (also referred to as *radix contours*) is highlighted by the nasal light reflex and are ideally symmetric (Fig. 181.6).

Dorsal Projection

The nose projects anteriorly from the face, with its forward thrust orthogonal to the facial plane and parallel to the midsagittal plane. Quantification of nasal projection is a critical component of the rhinoplastic evaluation, yet of the many methods previously described, none specifically address *dorsal projection* (i.e., dorsal height) (10–12). Determination of proper tip projection using Crumley's method, however, utilizes the geometry of the 3:4:5 triangle; that is, projection of the nasal tip should equal three-fifths (0.6) the length from the nasion to the tip-defining point. This method can be used simultaneously to yield the ideal dorsal projection at any point along the dorsum,

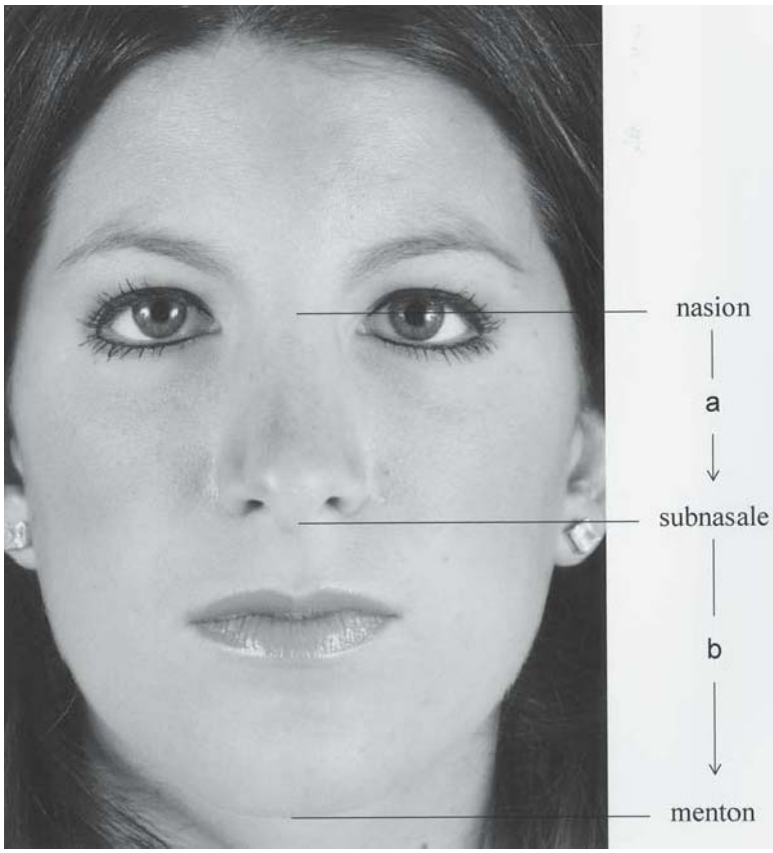

Figure 181.5 Determination of nasal length using the nasion, subnasale, and menton: ideally $a = {}^{3}/_{4}\ b$.

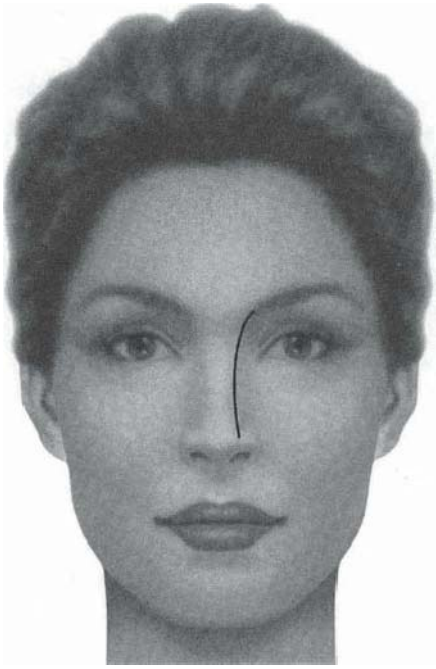

Figure 181.6 Brow–tip aesthetic line. (From Orten SS, Hilger PA. Facial analysis of the rhinoplasty patient. In: Papel ID, ed. *Facial plastic and reconstructive surgery*, 2nd ed. Stuttgart, Germany: Thieme, 2002:361, with permission.)

because the proportions of a 3:4:5 triangle are constant (Fig. 181.7). If dorsal projection exceeds this limit (0.6), it is indicative of the presence of a dorsal hump. Because a slight dorsal concavity can be attractive, dorsal projection just less than this limit is allowable, but a significantly lower measurement could be indicative of a saddle-nose deformity.

DEFECTS OF THE NASAL VAULTS

Bony Vault Defects

Most deformities involving the bony vault arise from blunt trauma (Table 181.1). Fractured nasal bones can be comminuted and/or displaced, often resulting in an unsightly twist, depression, spur, or hump. Frequently, the skin overlying the bony dorsum is lacerated causing additional deformity by the presence of cicatrix and adherence of the dermis to the nasal bone periosteum. Severe fractures such as nasoorbital ethmoid (NOE) fractures are often quite disfiguring due to retrodisplacement of the nasal bones, deprojection and flattening of the nasal dorsum, and shortening of the nose. The resultant telescopic defect is often associated with traumatic telecanthus due to the disruption of the medial canthal tendon insertion on the nasal bones. Trauma involving the bony vault will commonly contribute to functional deficits if the keystone area, the septum, or the middle vault is also affected. Less common causes of upper vault deformity include prior rhinoplasty, neoplasia, and congenital anomalies (13,14).

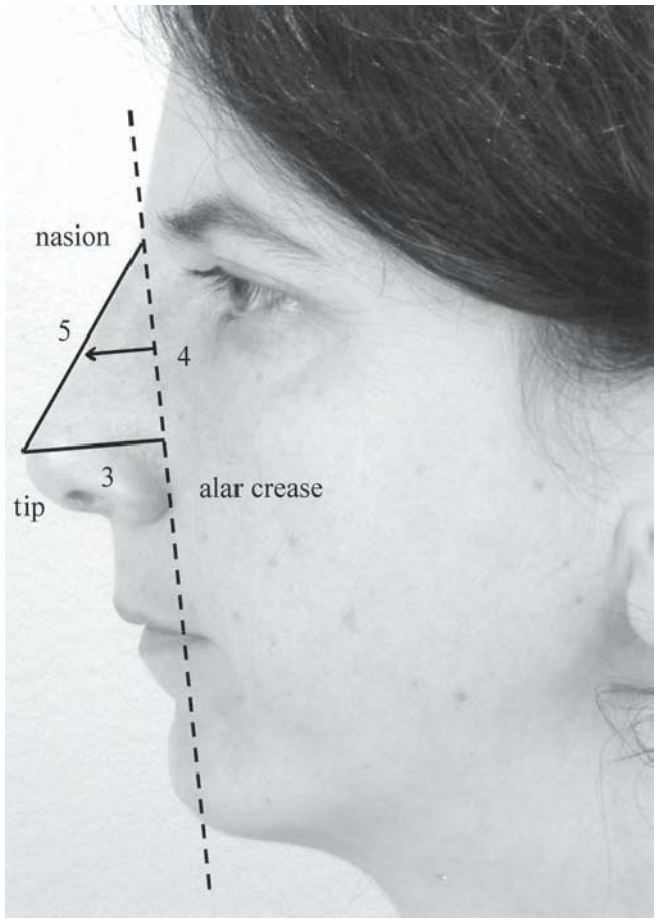

Figure 181.7 Determination of ideal dorsal projection using Crumley's tip projection analysis. At any point along the dorsum, the ratio of dorsal projection to the distance from the nasion should equal 3/5 (0.6).

Cartilaginous Vault Defects

Deformity of the middle nasal vault can be more complex than that of the bony vault because it is frequently accompanied by internal nasal deformity contributing to airway compromise. The internal nasal valve occurs near the junction of the upper lateral cartilages and the dorsal septum and is often weakened or narrowed subsequent to

TABLE 181.1 NASAL VAULT DEFECTS

trauma affecting the middle vault. Furthermore, the soft tissue nature of the middle vault makes it susceptible to deformity caused by other etiologies, including unrecognized birth trauma, infections, inflammatory diseases, or autoimmune processes (15–17).

Treatment of the middle vault in rhinoplasty was for many years considered little more than removal of a hump deformity. In the 1980s, however, surgeons began to describe numerous long-term complications of this limited approach, including the inverted-V deformity, nasal valve collapse, open roof deformity, and pollybeak deformity. As a result, rhinoplasty techniques were modified to avoid these problems (18,19).

MANAGEMENT OF THE CARTILAGINOUS VAULT

Surgical correction of the middle vault involves correction of existing deformities, while ever mindful of additional deformity prevention. When certain risk factors are present, such as short nasal bones, weak upper lateral cartilages, thin skin, narrow bony pyramid, or previous trauma or surgery, preventative action may be required utilizing cartilage grafting, precise structural realignment, and fixation of nasal valve structures.

Correction of middle vault starts with septoplasty. The old saying "as the septum goes, so goes the nose" indicates the importance of straightening the central strut of the nose. With the goal of making the dorsal septum as straight as possible, the open approach is often used. Accessing the septum from above via the separation of the medial crura of the lower lateral cartilages allows better exposure than the traditional endonasal approach (20). Further separation of the upper lateral cartilages from the dorsal septum results in maximal septal exposure. The deviated portions of the quadrangular cartilage and perpendicular plate of the ethmoid bone are removed, making sure that 1 cm dorsal and caudal struts are maintained. Wide mucoperichondrial elevation, weakening incisions, wedge excisions, and sutured struts are adjuncts useful in straightening the deviated septum (21).

Spreader grafts are probably the next most common corrective modality used for middle vault rehabilitation. First described by Sheen and Sheen (22), these rectangular cartilage grafts are placed between the junctions of the upper lateral cartilages and septum to widen and stabilize the nasal valve. Spreader grafts not only lateralize the upper lateral cartilages but also strengthen the middle vault to resist the inward motion on inspiration associated with Bernoulli principle. They can be placed either through open or closed rhinoplasty techniques but are easier to stabilize with direct sutures via the open approach. Septal cartilage is the most frequently used grafting material, but auricular cartilage may be used if septum is not available. Spreader grafts can also be used for aesthetic purposes. For patients with unilateral middle vault depressions, a single spreader graft can elevate and lateralize the upper lateral cartilage to restore symmetry.

In many revision rhinoplasty cases involving middle vault pathology, separation of the septum and upper lateral cartilages has occurred due to prior hump removal. There is usually fibrous connective tissue present instead of the native cartilaginous junction. Therefore, preservation of the mucoperichondrium and creation of a pocket for graft placement through the open approach are usually preferred. If the upper lateral cartilages are fused with the septum in the internal nasal valve area, sharp dissection with an elevator will preserve the mucoperichondrium and maintain stability. In cases in which the upper lateral cartilages have been almost completely resected, conchal cartilage onlay grafts may be needed in addition to spreader grafts to augment lateral support or camouflage depressions. The grafts are carved, aligned, and fixed into position with 5-0 PDS (Polydioxanone Ethicon, Somerville, NJ) mattress sutures. Most spreader grafts are 1.5 to 2.5 cm in length and 1 to 3 mm in width. In general, the grafts should run along the dorsal septum from below the bony cartilaginous junction to the anterior septal angle. In severe cases, the grafts may be layered to provide additional bulk. Grafts of unequal width may also be used to correct asymmetries in the middle vault. Spreader grafts can also be used as internal splints to help straighten a caudal septal deflection. The technique of spreader graft placement and fixation is demonstrated in Figures 181.8 to 181.11. Placement of spreader grafts is greatly facilitated by placement of a 30-gauge needle through the cartilage complex while suturing.

A corollary to spreader grafting that deserves mention is reverse spreader grafting. This technique can be useful in patients with an overly broad middle vault, minimal nasal obstruction, and no nasal valve collapse. In these cases, patients can benefit from reduction of the horizontal width of the cartilaginous dorsum, which can be thought of as the reverse of spreader grafts (23).

Additional methods to augment the function of the nasal valve involve the placement of alar batten grafts, butterfly grafts, and various suture methods. Schlosser and Park (24) described the use of 5-0 clear nylon flaring sutures that span the upper lateral cartilages and septum horizontally. Tightening the suture theoretically increases the angle of the internal nasal valve and therefore improves nasal airflow. Their study indicated that flaring sutures used concomitantly with spreader grafts increase airflow more than the use of spreader grafts alone. Other suture techniques such as tip-lifting sutures, or valve maneuvers like internal valve M-plasty or lateral crural J-flap, can also be useful adjuncts but are outside the scope of this chapter.

Patients with saddle-nose deformity frequently have middle vault collapse without soft tissue support, commonly due to a large septal perforation. Fixation of a dorsal graft helps to enhance dorsal projection, support the soft tissues, and restore the integrity of the nasal valve. Calvarial bone secured with a lag screw or rib cartilage

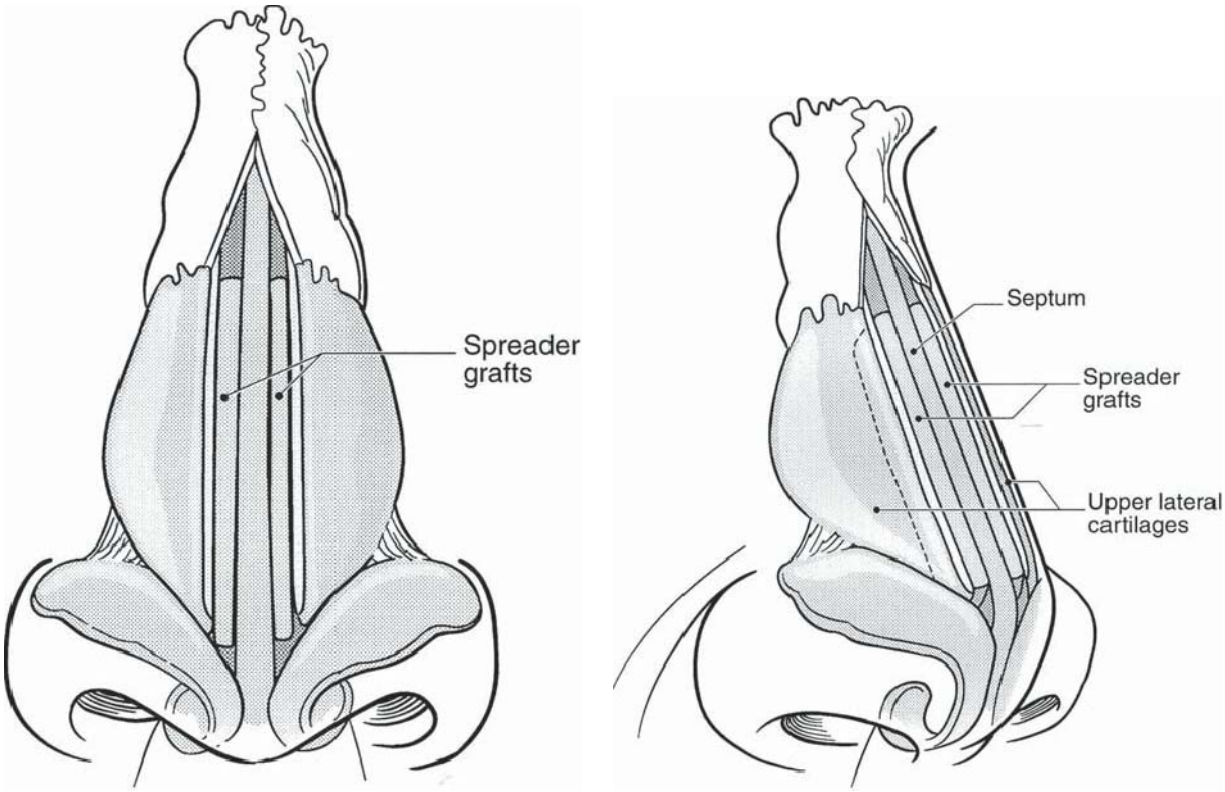

Figure 181.8 Placement of spreader grafts between septum and upper lateral cartilages. (From Papel ID. Management of the middle vault. In: Papel ID, ed. *Facial plastic and reconstructive surgery*, 2nd ed. Stuttgart, Germany: Thieme, 2002:409, with permission.)

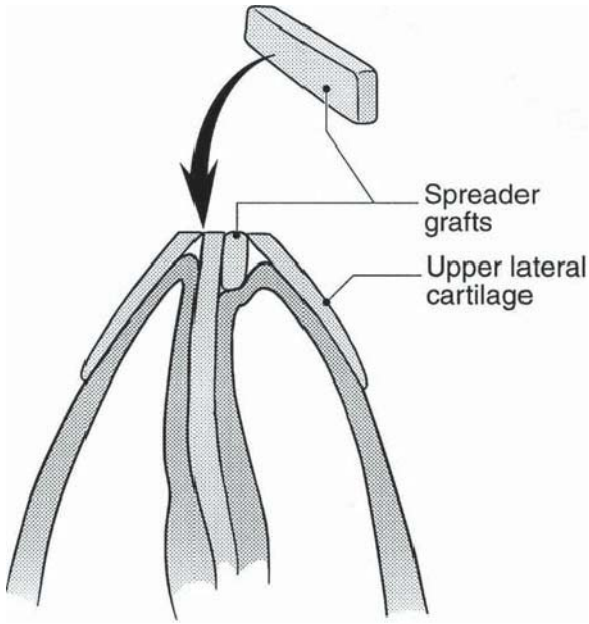

Figure 181.9 Placement of spreader graft lateralizes and elevates the upper lateral cartilage, widening the middle vault. (From Papel ID. Management of the middle vault. In: Papel ID, ed. *Facial plastic and reconstructive surgery*, 2nd ed. Stuttgart, Germany: Thieme, 2002:409, Fig. 35-5, with permission.)

secured with sutures has been very useful in these patients (25,26). In addition, dorsal calvarial grafts can serve as anchors for other reconstructive grafts (27). In some cases, the use of crushed cartilage or AlloDerm (LifeCell Corp., Branchburg, NJ) over the dorsum and graft material can help smooth an irregular profile.

The pollybeak deformity is a complex nasal deformity with multiple etiologies that deserves special mention. It is caused by *relative* underprojection of the nasal tip with regard to the projection of the dorsum. It is important to understand that a pollybeak can occur, therefore, when the tip is either *correctly projected* or *underprojected*. If tip projection is aesthetically correct but the dorsum remains overprojected, a pollybeak deformity is present. Conversely, a pollybeak results when dorsal projection is aesthetically correct but the tip is underprojected. A pollybeak deformity can occur naturally, or as the result of prior rhinoplasty, with insufficient lowering of the cartilaginous dorsum, excessive reduction of the bony dorsum, disruption of tip support without reconstitution, excessive tip deprojection, or inappropriate derotation of the tip. As such, there are different management strategies for minimizing the incidence of pollybeak, depending on the nature of the deformity. The important point is that the rhinoplasty surgeon recognizes the importance of the critical relation between tip projection and dorsal projection during rhinoplasty and maintains adequate tip projection when altering the dorsum.

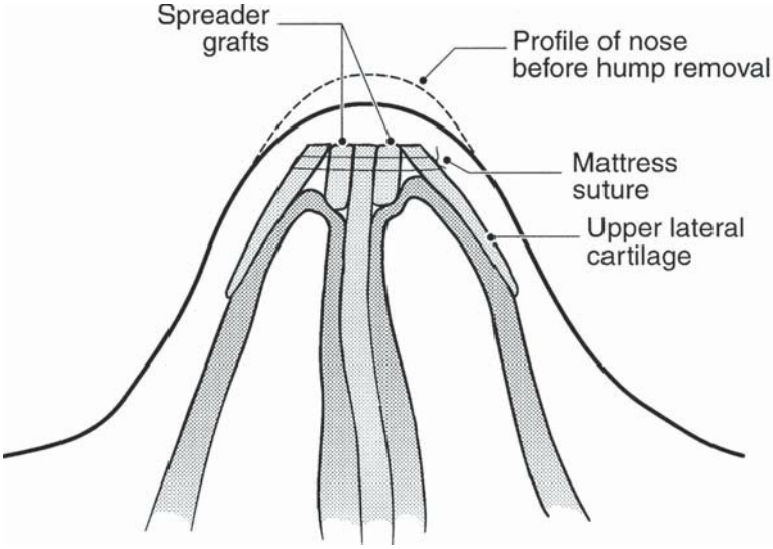

Figure 181.10 Spreader grafts in place and fixed with mattress sutures. The original dorsal height is identified. (From Papel ID. Management of the middle vault. In: Papel ID, ed. *Facial plastic and reconstructive surgery*, 2nd ed. Stuttgart, Germany: Thieme, 2002:409, with permission.)

MANAGEMENT OF THE BONY VAULT

Deformity of the upper nasal vault represents a challenge to the rhinoplasty surgeon, requiring thorough preoperative evaluation and careful surgical technique to manage. Improper or incomplete treatment of the bony vault may lead to suboptimal results, including persistence of existing defects or the creation of new ones. The presence of iatrogenic deformities listed in Table 181.1 bears witness to this. Surgical treatment of the bony vault should aim to accomplish the following: (a) establishment of appropriate dorsal projection, (b) creation of a smooth dorsal contour free of bony irregularity, (c) correction of nasal width, and (d) straightening of the crooked nose. Techniques used to accomplish these aims include hump reduction, osteotomies, and grafting.

Hump Reduction

John Orlando Roe (1848 to 1915) provided the modern age with the first account of dorsal defect correction in 1891 (Fig. 181.12) (28). Regional dorsal overprojection is managed with wide soft tissue envelope elevation and the removal of portions of the nasal bones. This can be done either through an open or closed approach. Adequate exposure must be balanced with the maintenance of soft tissue

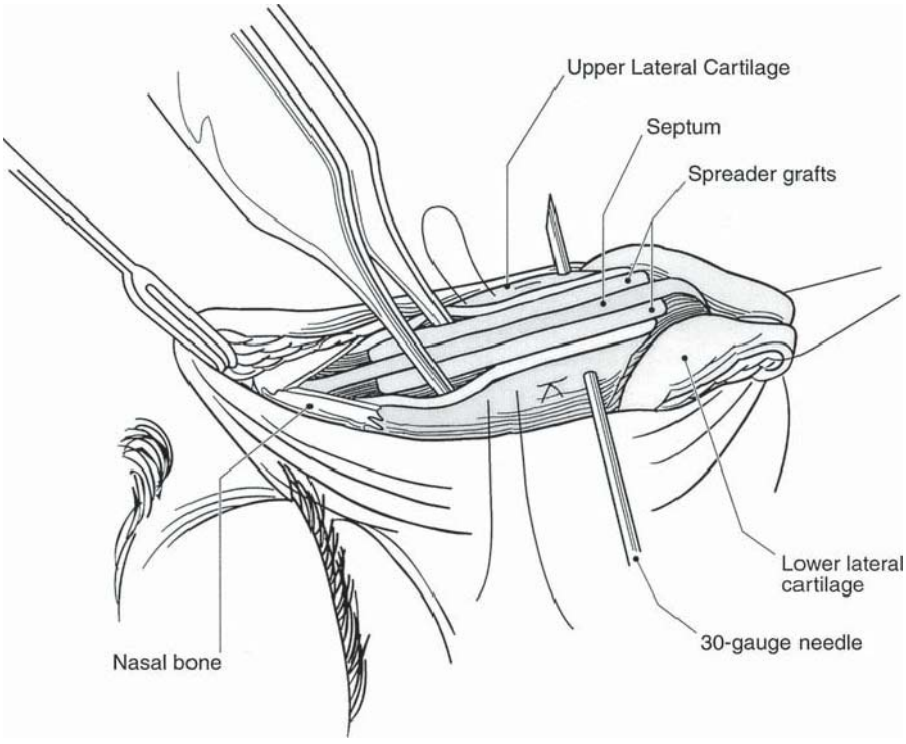

Figure 181.11 Demonstration of mattress suture fixation and use of 30-gauge needle for stabilization. (From Papel ID. Management of the middle vault. In: Papel ID, ed. *Facial plastic and reconstructive surgery*, 2nd ed. Stuttgart, Germany: Thieme, 2002:409, Fig. 35-7, with permission.)

Figure 181.12 John Orlando Roe patient: before **(A)** and after **(B)** dorsal hump removal (1891). (From Lam SM. John Orlando Roe: father of aesthetic rhinoplasty. *Arch Facial Plast Surg* 2002;4: 122–123, with permission.)

support, and it must be remembered that the upper lateral cartilages insert deep to the caudal margin of the nasal bones. Exquisite care must be taken not to disarticulate this union. The best way to avoid this is to elevate the nasal bone periosteum using a Joseph elevator starting from a point 1 to 2 mm superior to the rhinion (29). Bone removal is subsequently accomplished with a double-guarded osteotome or a carbide tungsten pull rasp, depending on the amount of bone to be removed. After sharp incision of the cartilaginous component, large humps typically require removal with the osteotome. Care should be taken to follow the planned trajectory and not make an oblique cut by straying laterally or canting the osteotome (Fig. 181.13). Refinements can then be performed by rasping just off midline in a slightly oblique manner so as not to avulse the upper lateral cartilages (30). It must always be remembered that overly aggressive bony and cartilaginous dorsal reduction can lead to a scooped nasal appearance and even *the saddle-nose deformity*.

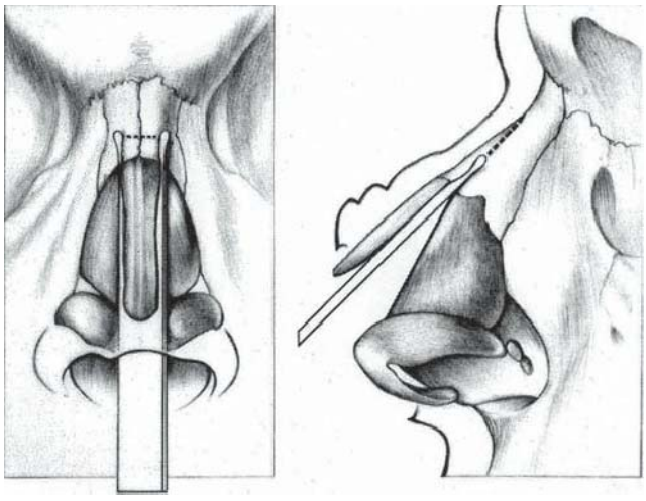

Figure 181.13 Removal of dorsal excess. (From Mostafour SP, Murakami CS, Larrabee WF Jr. Management of the bony nasal vault. In: Papel ID, ed. *Facial plastic and reconstructive surgery*, 2nd ed. Stuttgart, Germany: Thieme, 2002:403, with permission.)

Osteotomies

Osteotomies have evolved greatly since the time of Jacques Joseph (1865 to 1934), one of the rhinoplasty pioneers who touted their importance (31). Early techniques were fraught with nasal airway compromise largely due to a trajectory that caused wide disruption of periosteum and release of lower lateral cartilage lateral suspensory ligaments. Modifications have led to the emergence of modern techniques that place equal importance on preservation of the nasal airway and aesthetic improvement, in accord with the dual tenet of the rhinoplasty operation (32,33).

Osteotomies are commonly used to improve irregularities in the brow–tip aesthetic line and correct open roof deformities (diastasis of the nasal bones) associated with bony dorsum reduction. They can be performed laterally, medially, or intermediately. Lateral osteotomies should be limited to the thin bone of the pyriform aperture, lateral to the anterior margin of the ascending maxillary processes. If too far lateral, the thick bone at the nasofacial transition will be encountered, rather than the average 2.5-mm thickness typically encountered along the osteotomy path (34).

Lateral osteotomies can be linear or perforating, internal or external. The ideal trajectory is described as "high–low–high," which indicates the anteroposterior position on the nasal pyramid. A standard lateral osteotomy is a linear, internal cut that is initiated with a mucosal stab incision made just lateral to the anterior face of the inferior turbinate. The curved, guarded 4-mm osteotome is placed into the incision on the margin of the pyriform aperture, at about a 45-degree angle to the facial plane, or roughly perpendicular to the face of the aperture (Fig. 181.14). Preservation of the inferior segment of the pyriform maintains the lateral suspensory ligaments and width important for the nasal airway. Soon after the initial cut, the osteotome should be transitioned roughly parallel to the facial plane and directed toward the medial canthal area. The osteotomy should then curve anteriorly and superiorly to terminate at the level of the medial canthus, midway between the dorsal line and the medial canthus. The telltale sound of the osteotome meeting the thicker frontal bone is indicative of the proper stopping point. The osteotomy is completed with pronation and medialization of the osteotome, causing back-fracture across the superior aspect of the nasal bone. Elevation of the periosteum in this vicinity liberates the nasal bones from the soft tissue envelope, allowing the osteotomized bone to heal free of the influence of soft tissue contracture. If the back-fracture is incomplete or inadequate, it can be augmented percutaneously using a 2-mm osteotome. Alternatively, the entire back-fracture can be completed percutaneously. If the osteotomy extends superior to the medial canthus, there is greater risk of creating a *rocker deformity*, which occurs when the nasal bone inferior to the osteotomy sinks relative to the bone superior to the cut. Should this occur, steps must be taken to camouflage the step off or replace the

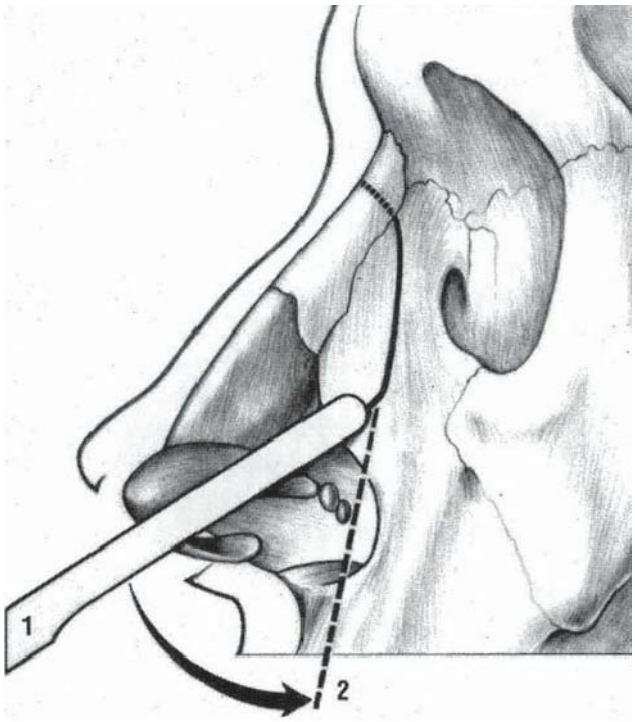

Figure 181.14 The lateral osteotomy is initiated at the anterior face of the inferior turbinate, initially perpendicular to the plane of the pyriform aperture (position *1*). The osteotomy is then transitioned (position *2*) and carried to the medial canthal area. (From Mostafour SP, Murakami CS, Larrabee WF Jr. Management of the bony nasal vault. In: Papel ID, ed. *Facial plastic and reconstructive surgery*, 2nd ed. Stuttgart, Germany: Thieme, 2002:404, with permission.)

malpositioned bone, and wait until the bone heals before attempting further osteotomy.

Perforating lateral osteotomies can be performed either internally (transnasally) or externally (percutaneously). The perforating technique is the ideal method to complete an exact osteotomy with minimal trauma. It is preferred when maintenance of support is critical, such as in revision rhinoplasty or short nasal bones, because there is far less disruption of periosteal support and the intact periosteum stabilizes and splints the mobilized segments, enhancing precise healing (35,36). A series of perforations are made at fixed intervals along the desired fracture trajectory and then completed with minimal manual manipulation. The intranasal perforating osteotomy is useful to widen the pyriform aperture by displacing the bones laterally (37).

Medial and intermediate osteotomies should be used judiciously; however, they can be essential when the pyriform is very thick, the nose is significantly deviated, or a very large nose needs to be reduced. Both medial and intermediate osteotomies are usually performed transnasally with a 3-mm osteotome. Medial osteotomies are initiated on the medial aspect of the caudal margin of the nasal bones near the septum. This is very near the keystone area of the nasal vaults, so considerable care must be taken, for disruption of the connection between the caudal margin

Figure 181.15 An intermediate osteotomy is marked on the skin and the inferior edge of the bone is noted. A percutaneous method is used in a perforating manner.

of the nasal bones and the cephalic margin of the upper lateral cartilages is the cause of *the inverted-V deformity* and its accompanying nasal obstruction. The percutaneous perforation technique can be used to perform medial osteotomies to further ensure preservation of the keystone. The trajectory of the fracture is superolateral, meeting with the back-fracture of the previously performed lateral osteotomy. If further correction is needed, intermediate osteotomies can also be performed. The intermediate osteotomy is also initiated on the caudal margin of the nasal bones, intermediate to the medial and lateral osteotomies. The trajectory should parallel the lateral osteotomy and meet with the superior back-fracture. Because intermediate osteotomies are difficult to execute if the lateral bone has already been mobilized, they are best performed prior to lateral osteotomies. Figure 181.15 demonstrates a percutaneous technique for an intermediate osteotomy. Note how the bony cartilaginous margin is marked to prevent damage to the supporting system (Fig. 181.15).

It is often helpful to plan the steps needed to reshape the upper two-thirds of the nose. Drawing the lines of planned osteotomies and indicating those areas to be grafted or reduced will help guide the operation in a logical manner. This can be very helpful to keep the procedure on track, especially after edema has occurred and the original contours may not be easily visible (Fig. 181.16).

Grafts

Contemporary grafts useful in treatment of the bony vault include radix grafts, onlay grafts, and anchored bone grafts. Radix grafts serve to increase the projection of the nasofrontal trough, correcting the excessively deep nasion. If septal or auricular cartilage is readily accessible, it can be used either as a single morselized piece or multiple

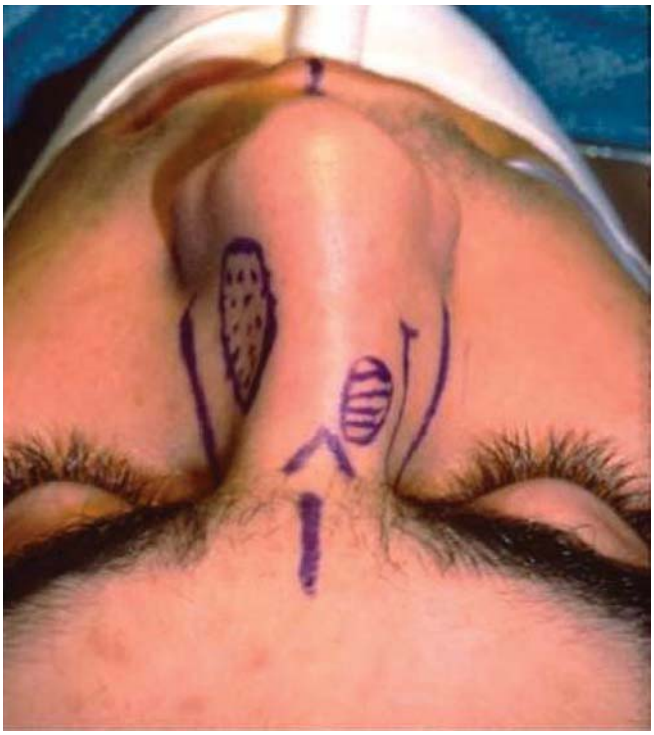

Figure 181.16 The surgical plan is marked on the skin prior to local anesthetic infiltration. Areas of grafting, reduction, and osteotomy are marked.

fragments sutured together as a plumping graft (38). The graft is placed either superficial or deep to the nasal bone periosteum and held in place by the overlying skin envelope. Although AlloDerm can also be used as a radix graft, it is perhaps more useful as a dorsal onlay graft to camouflage small irregularities as well as to add height. When significant bony defects are present, as after cancer resection or NOE-telescoping nasal deformity, calvarial bone grafts may be required to reconstruct the upper vault. These grafts are cantilevered off the frontal bone and anchored precisely with titanium screws.

CONCLUSION

Facial aesthetics and attractiveness rely in large part on the appearance of the nose. Deformities affecting the nasal vaults are distinct and independent from those affecting the nasal tip and contribute not only to unsightly appearance but also to improper nasal function. Building on the past experience of prior rhinoplasty surgeons, surgical techniques dealing with nasal vault deformities have evolved, ever mindful that restoration of proper anatomic vault relations significantly enhances the appearance of the nose and nasal function. The contemporary rhinoplasty surgeon must be facile with analysis and management of the bony and cartilaginous nasal vaults that comprise the upper two-thirds of the nose and be able to integrate this into management of the nasal tip for successful performance of the rhinoplasty operation.

HIGHLIGHTS

- The internal nasal valve is located at the junction of the upper lateral cartilages and the dorsal septum.
- Spreader grafts between the upper lateral cartilages and septum may widen and stabilize the valve.
- The valve may also be augmented with batten grafts, butterfly grafts, and suture methods.
- The pollybeak deformity is relative under projection of the nasal tip relative to the dorsum.
- Upper vault deformity is managed with hump reduction, osteotomies, and grafting.
- The insertion of the upper lateral cartilages on the caudal margin of the nasal bones must not be disarticulated.

182 Nasal Tip Surgery

Tatiana K. Dixon *Dean M. Toriumi*

Creating a natural nasal tip contour is a complex task and requires a three-dimensional approach. The surgeon must have a clear understanding of what looks normal and which methods should be used to attain that natural contour. The lower third of the nose is composed of multiple subunits (tip, columella, facets, and alae), and the curvilinear surface transitions between these nasal subunits create highlights and shadows. Even the slightest concavity or asymmetry in the tip results in unnaturally positioned shadows, which detract from the person's appearance on frontal view. When contouring the nasal tip, the surgeon should focus more on creating favorable shadows and highlights and less on narrowing. Simply narrowing the nasal tip may create abnormal shadowing between the nasal tip and alae resulting in a pinched-tip look. Careful consideration of the underlying anatomic structures and proper use of suturing and repositioning techniques in combination with cartilage grafting will help create favorable, natural-appearing tip contours that will better withstand the forces of scar contracture over time (1).

ANALYSIS AND DIAGNOSIS

Analysis of the tip, which is only one component of the nasal examination, is not undertaken in isolation. For the sake of brevity, this chapter focuses only on the contribution of the tip to the form and function of the nose. The reader is encouraged to consult another source (Chapter 179) for a thorough overview of nasal analysis.

Before undertaking an intelligent analysis of the nasal tip, it is imperative to have a mastery of nasal anatomy as well as a clear understanding of the ideal contours and relationships of the nose (Figs. 182.1 to 182.6).

When evaluating the tip, the surgeon should attempt to visualize the underlying structures by inspecting the skin. The first step is to try to quantify the thickness of the skin envelope. Most surgeons classify patients into thin, medium, and thick skin categories. This can be estimated by inspection and palpation of the skin by rolling it between the thumb and index finger. When assessing skin thickness, freckles are a reliable indicator of thin skin (2). Thick skin tends to be more sebaceous and have thick nostril rims and less defined alar facets.

Understanding the implications of skin thickness should radically alter the surgical plan with an emphasis on long-term results. Thin-skinned patients require a high degree of precision and symmetry without sharp edges of bone or cartilage, lest they be visible shortly after surgery. Thin-skinned patients should also be advised that they have a greater risk of developing small, visible asymmetries than patients with thicker skin. Conversely, they will enjoy a more rapid course of healing than their thick-skinned counterparts.

Thick-skinned patients, on the other hand, have fewer surgical options than those with thin skin. It is critical that the surgeon not promise a result that is impossible to attain. For example, thick-skinned patients often request a more refined tip. Although a bulbous tip can be improved, a thick-skinned nose will not have defined soft triangles or a "chiseled" appearance postoperatively, despite the surgeon's efforts. Many thick-skinned patients also have large noses and want them made smaller. Because a thick skin envelope will not contract to any significant degree, it is a mistake to expect that cartilage resection alone will refine the contour of the tip and result in a smaller nose. Counsel these patients that, although their tip can be refined, it often necessitates the use of grafts to stretch and refine the thick tip skin and therefore requires increasing projection to achieve that definition. This increase in projection will have the added benefit of being able to keep the dorsum of the nose high, which will increase the appearance of a narrow nose. Otherwise, they risk having a loose, ptotic, poorly supported tip. Too many patients with thick skin undergo multiple revisions wherein the revising surgeon

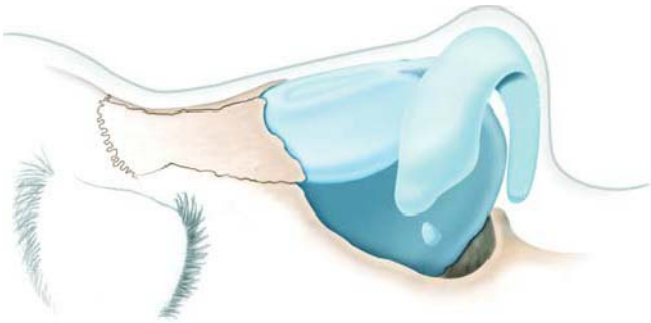

Figure 182.1 Lateral view of the structures of the nasal tip.

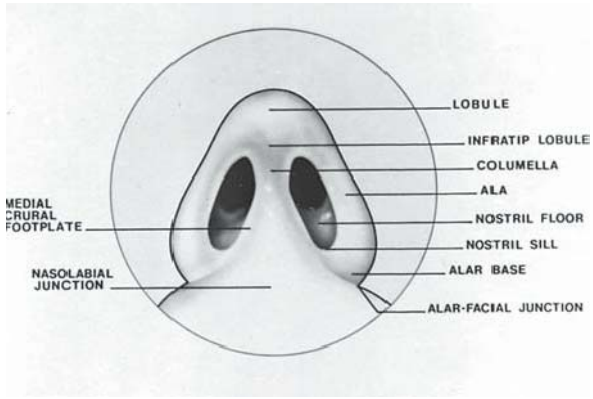

Figure 182.3 Anatomy and nomenclature of the nasal tip viewed from the basal aspect.

attempts to trim "just a little bit more," which only exacerbates the problem (Fig. 182.7).

Palpation of the tip and its ability to recoil when depressed can identify weak lower lateral cartilages or a low anterior septal angle (Fig. 182.8). The septum can also be palpated by placing the tip of the thumb and index finger in each of the nasal vestibules. This maneuver facilitates recognition of a weak or deviated caudal septum (2).

Evaluation of the tip must include assessment of the tip supporting structures. Anderson's tripod model of the nasal tip clarified the dynamics of altering tip support (3). In it, the conjoined medial crura represent one leg of the tripod and the lateral crura the other two. Tip position, therefore, is a consequence of the combined forces of the three legs of the tripod as well as the support provided by the caudal septum (Fig. 182.9). This model illustrates the variable contributions of the medial and lateral crural length when assessing projection, rotation, and the columella–labial angle.

The medial crura should be inspected by looking at the nasal base. Medial crural length has several surgical implications. Short medial crura provide little tip support and will require reinforcement to prevent postoperative loss of projection and counterrotation. If the surgeon intends to rotate the tip by performing a cephalic trim of the lateral crura, the poor support of short medial crura will preclude any meaningful cephalic rotation. Similarly, long medial crura may provide excellent tip support, but if the nose needs to be deprojected, techniques such as a full transfixion incision will have minimal impact. These long medial crura will likely need to be modified to deproject the nose. Any deficiencies in these major tip support mechanisms need to be addressed at the time of surgery.

Important parameters to assess when analyzing the lateral view of the nasal tip are projection and rotation. Assessment of tip projection must be undertaken in the context of the entire profile. The nasofrontal angle, depth of the radix, and chin all affect the appearance of nasal projection (Fig. 182.10). When examining an abnormally projected nose, the surgeon must identify where in the nose the projection is distorted. For instance, in an overprojected nose, the medial crura may be excessively long, the domes may be too tall, or the anterior septal angle

may be too anteriorly positioned. Similarly, short medial and lateral crura, a low anterior septal angle, flat domes, or a hypoplastic premaxilla can result in an underprojected nose. Sometimes these factors occur in combination. Therefore, although recognizing that a nose is over- or underprojected is an important first step, the appropriate treatment options are widely divergent depending on the reason for the deformity. Unless the surgeon can identify these subtleties, good results are only a product of chance.

Ideal rotation is 90 to 100 degrees in males and 100 to 120 degrees in females. This varies according to the height of the patient as shorter patients tolerate more

Figure 182.7 This patient had a bulbous tip and thick skin. After several reductive procedures, the tip is poorly supported and unrefined.

rotation and taller patients require less rotation to avoid seeing too much nostril on the frontal view. The perceived rotation is affected by the position and contour of the nasolabial angle. Another important component is the alar–columellar relationship, with approximately 2- to 4-mm columellar show being considered aesthetic. Lastly, the double break and supratip break are important components that must be maintained or created to ensure a

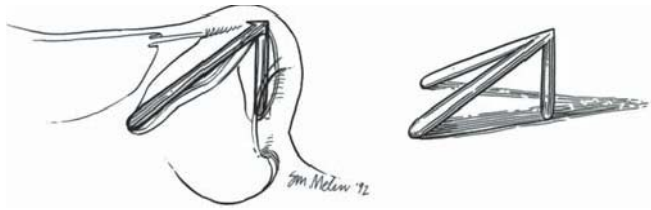

Figure 182.9 Tip position is a consequence of the combined forces of the three legs of the tripod as well as the support provided by the caudal septum.

natural appearance of the tip. The double break is formed by the natural divergence of the intermediate crura (Fig. 182.11), and the supratip break is the transition from the tip-defining point to the dorsum.

When assessing the frontal view, subtle highlights and shadows impart a three-dimensional perspective. First, the aesthetically pleasing nasal tip has a horizontally oriented tip highlight formed by the divergence of the intermediate crura and the paired domes (Fig. 182.12). The tip highlight should gradually transition to the alae without a deep shadow (1). The average width between tip-defining points is about 8 mm, but this can vary between 6 and 14 mm based on overall facial width, base width, and cultural norms (4). Of equal importance, there is a subtle shadow in the supratip region that continues laterally into the supra-alar groove, representing the supratip break. This shadow creates the appearance of a refined tip and is caused by the transition between the most projecting point of the domes and the more posteriorly positioned septum (1).

Tip deformities and nasal obstruction can be a result of irregularities in the shape and rigidity of the lower lateral cartilages. Two important and frequently overlooked

Figure 182.10 Demonstration of the value of chin augmentation associated with nasal tip surgery when microgenia accompanies the nasal deformity. Note how the increased postoperative chin projection helps to balance the lateral view and tip projection. The rhinoplasty involved dorsal hump reduction, nasal tip setback to decrease projection, and dome sutures with lateral crural strut grafts. **A**: Before surgery. **B**: After surgery.

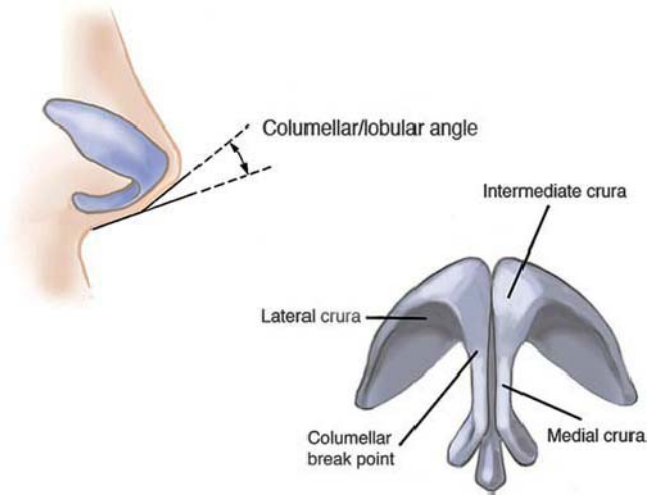

Figure 182.11 The double break is formed by the natural divergence of the intermediate crura. The columellar lobular angle is formed by the intermediate crura diverging into the lateral crura.

tip deformities are cephalically positioned lateral crura and internal curvature of the lateral crura. Cephalically positioned lateral crura are often the cause of a dynamic airway obstruction because of poor support of the lateral nasal wall. A hypermobile nasal sidewall is susceptible to collapse on inspiration, which narrows the internal nasal valve. Aesthetically, cephalic positioning of the lateral crura often appears as a bulbous tip with a "parentheses" appearance on frontal view (Fig. 182.13). This is because the shadow in the supratip area is lost due to

the underlying lateral crura, and due to poor lateral wall support, the horizontally oriented tip highlight does not extend onto the alae. The lateral crura may be too long and recurve into the airway creating a bulge on the internal vestibular surface of the lateral nasal wall (Fig. 182.14). This,

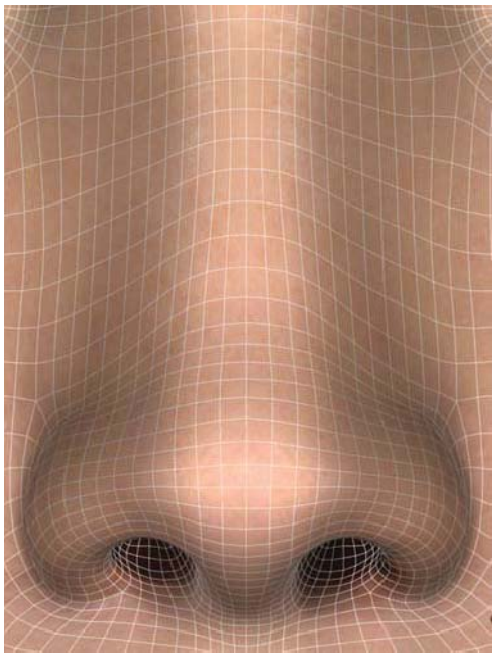

Figure 182.12 The aesthetically pleasing nasal tip has a horizontally oriented tip highlight that gradually transitions to the alae without a deep shadow. There is also a subtle shadow in the supratip region that continues laterally into the supra-alar groove, representing the supratip break.

too, diminishes lateral wall support and can cause a static obstruction. Before formulating a plan for operating on the nasal tip, the surgeon must first accurately analyze the underlying structure that is responsible for the patient's deformity.

PREOPERATIVE PLANNING

Standardized photography is mandatory for any surgeon committed to learning from experience. It also allows the surgeon to communicate more effectively with the patient about the goals and techniques of the planned operation. Computer imaging software permits morphing or side-by-side evaluation of the preoperative and planned postoperative states. In addition, many surgeons print the manipulated images to use as a guide during surgery. Please refer to Chapter 171 for a more detailed review of the use of photography in facial plastic surgery.

In the operating room, it is helpful to mark the patient before injecting local anesthetic. The distorting effects of local anesthesia and intraoperative edema can mask many of the asymmetries and contour irregularities that should be addressed by the surgery.

SURGICAL TECHNIQUES

Stabilizing the Nasal Base

Before meaningful changes can be made to the tip lobule, the surgeon must create a stable foundation at the nasal base. The nasal base is composed of the caudal septum and its soft tissue attachments to the lower lateral cartilages. The major tip support mechanisms are (a) the strength, size, and shape of the alar cartilages; (b) the attachment of the medial crura to the septum; and (c) the attachment between the cephalic edge of the lower lateral cartilages to the upper lateral cartilages (Fig. 182.2). Patients at risk for postoperative loss of tip projection are those with weak lower lateral cartilages, a short caudal septum, and short medial crura. If the base is not stabilized, the surgeon must overcorrect projection and rotation in anticipation of postoperative loss of projection. This degree of overcorrection is based on the surgeon's best estimate of what he believes the postoperative loss in projection will be. Proper stabilization of the base enables the surgeon to place the nasal tip in the desired position and avoids postoperative loss of tip projection (1). Precise, predictable control of tip projection therefore removes much of the guesswork from rhinoplasty. The hallmark of a tip that is poorly supported is the pollybeak deformity. When the tip deprojects postoperatively, the tip–supratip relationship is reversed. The ideally concave supratip break becomes an unattractive convexity. This tempts some surgeons to overresect the septum in order to prevent this deformity. This, however, also results in an unnatural outcome where the nose is inadequately projected and wide or poorly defined on the frontal view.

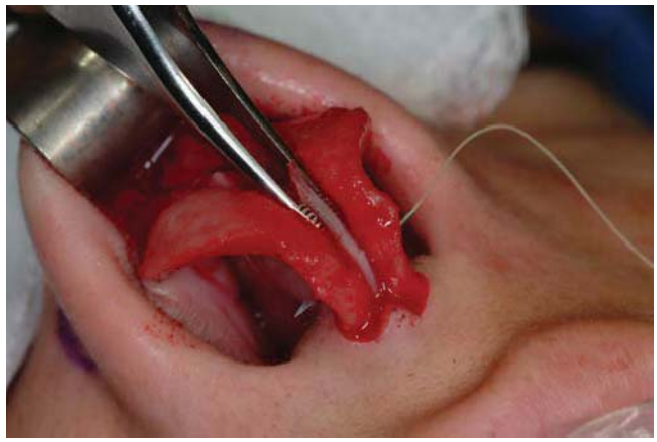

Figure 182.15 A columellar strut is placed by dissecting a pocket between the medial crura and suturing it in the midline.

Detailed examination of the nasal base is important to identify the necessary steps to stabilize the base and set the tip in the desired location. If the base is well supported by long medial crura, and the alar–columellar relationship is appropriate, a sutured in place columellar strut can effectively stabilize the base (4,5). This is also a good technique for reinforcing medial crura that are in good position but are buckled or warped. A columellar strut should be 5 to 12 mm in length and 3 to 6 mm wide. Ideally, a strut is less than 3 mm thick. It is placed by dissecting a pocket between the medial crura and suturing it in the midline (Fig. 182.15). The strut should not extend to the nasal spine because this can lead to clicking if it slides from side to side. A floating strut will not increase projection but will support the medial crura in their contribution to a stable nasal base.

In contrast to a floating columellar strut, an extended columellar strut is beneficial to use in patients with an underprojected tip caused by poor tip support. The extended columellar strut usually sits on the premaxilla or is suture fixated into a notch made in the nasal spine (Fig.182.16). Similarly, an extended strut can interdigitate with a premaxillary graft. This is especially helpful in patients whose poor projection is a result of inadequate tip support and a deficient premaxilla, such as those with a cleft-lip nasal deformity. The medial crura can then be advanced anteriorly and fixed in a more projected position. Often, the soft tissue over the anterior nasal spine needs to be dissected free to permit advancement of the nasal base. This also has the effect of softening the nasolabial angle. A consequence of fixing the extended columellar strut to the nasal spine is that it may prohibit upward movement of the upper lip creating a crease in the upper lip when the patient smiles. Patients with an exaggerated upward elevation of the corner of their mouth when they smile are at the highest risk for a change in their smile with an extended columellar strut.

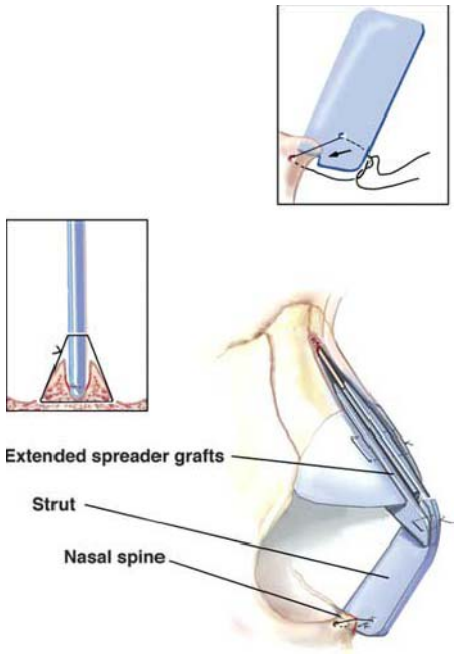

Figure 182.16 The extended columellar strut usually sits on the premaxilla or is suture fixated into a notch made in the nasal spine. The strut is placed end to end with the septum and stabilized with extended spreader grafts.

Patients who have a hanging columella and an overly long caudal septum are good candidates for fixation of the medial crura to the septum. This is done by dissecting between the medial crura to provide access to the septum. A septoplasty is easily performed through this approach by elevating bilateral mucoperichondrial flaps. The medial crura are then positioned on the caudal septum in a tongue-in-groove manner with a 4-0 chromic mattress suture (6) (Fig. 182.17). Once the tip position is satisfactory, a 5-0 polydioxanone (PDS) suture is passed through the medial surfaces of the medial crura and the septum. A 4-0 plain gut suture on a Keith needle is then used to quilt the septal mucoperichondrial flaps and redistribute any excess mucosa.
